of
MYCOLOGY

Editor in Chief
ÓSCAR ZARAGOZA
Honorary Editor
ARTURO CASADEVALL

ENCYCLOPEDIA OF MYCOLOGY

Volume 1

ENCYCLOPEDIA OF MYCOLOGY

EDITOR IN CHIEF

Óscar Zaragoza

National Centre for Microbiology, Madrid, Spain

Honorary Editor

Arturo Casadevall

Johns Hopkins Bloomberg School of Public Health, Baltimore, USA

Section Editors

Raffaella Balestrini

IPSP, National Research Council of Italy, Torino, Italy

Miia Mäkelä

University of Helsinki, Helsinki, Finland

Joshua Nosanchuk

Albert Einstein College of Medicine, New York, USA

Carla Viegas

Polytechnique Institute of Lisbon, Lisbon, Portugal

Alfredo Vizzini

University of Torino, Torino, Italy

Ronald P de Vries

Utrecht University, Utrecht, The Netherlands

VOLUME 1

Next Generation Sequencing: Transcriptomics <i>Fabiano Sillo</i>	1
The Cell Wall of Medically Relevant Yeasts and Molds <i>Manuela Gómez-Gaviria, Laura C García-Carnero, Alma K Tamez-Castrellón, and Héctor M Mora-Montes</i>	12
The Fungal Chitinases <i>Georgios Tzelepis and Magnus Karlsson</i>	23
GTPases in Hyphal Growth <i>Bianca Ranocchi and Antonella Amicucci</i>	32
Membrane Transporters, an Overview of the Arbuscular Mycorrhizal Fungal Transportome <i>Nuria Ferrol</i>	44
Fungal Secondary Metabolism <i>Francesco Vinale, Krishnapillai Sivasithamparam, Susanne Zeilinger, and Santiago Gutiérrez</i>	54
Mycotoxins and Mycotoxigenic Fungi: Risk and Management. A Challenge for Future Global Food Safety and Security <i>Claudio Altomare, Antonio F Logrieco, and Antonia Gallo</i>	64
RNA Interference in Fungi <i>Alessandro Silvestri and Luisa Lanfranco</i>	94
The MAP Kinase Network As the Nervous System of Fungi <i>I Correia, D Prieto, R Alonso-Monge, J Pla, and E Román</i>	102
Communication With Plants <i>Marzia Beccaccioli, Valeria Scala, and Massimo Reverberi</i>	114
Genome Evolution of Fungal Plant Pathogens <i>Maria Aragona, Alessandro Infantino, Maria Teresa Valente, Alessandro Grottoli, and Anita Haegi</i>	123
Mycoviruses: A Hidden World Within Fungi <i>Luca Nerva and Walter Chitarra</i>	134
Transposable Elements in Fungi: Coevolution With the Host Genome Shapes, Genome Architecture, Plasticity and Adaptation <i>Cécile Lorrain, Ursula Oggenfuss, Daniel Croll, Sebastien Duplessis, and Eva Stukenbrock</i>	142

Aspergilli, More Than Just Fungi: Shaping the Last Decades of Model Systems <i>Francesca Degola</i>	156
Proteomics in Mycorrhizal and Plant Pathogenic Fungi <i>Federico Vita and Stefano Ghignone</i>	164
Host-Induced Stress Response in Human Pathogenic Fungi <i>Romeu Viana, Pedro Pais, Mafalda Cavalheiro, Mónica Galocha, and Miguel C Teixeira</i>	182
Biodegradation of Aromatic Toxic Pollutants by White Rot Fungi <i>Yitzhak Hadar</i>	197
Fungal Chitin and Chitosan <i>Mostafa M Abo Elsoud</i>	205
Chitin Synthases in Fungi <i>Weiguo Fang</i>	218
Glucose Metabolism and Use of Alternative Carbon Sources in Medically-Important Fungi <i>Shu Yih Chew and Leslie Thian Lung Than</i>	220
Ergosterol Synthesis <i>Somanon Bhattacharya</i>	230
Fungal Volatile Organic Compounds <i>Andrea Martinez and Joan W Bennett</i>	239
Outline of Ascomycota <i>Nalin N Wijayawardene, Kevin D Hyde, and Dong-Qin Dai</i>	246
Structure and Development of Ascomata <i>Chitrabhanu S Bhunjun, Chayanard Phukhamsakda, and Kevin D Hyde</i>	255
Laboulbeniomycetes, Enigmatic Fungi With a Turbulent Taxonomic History <i>Danny Haelewaters, Michał Gorczak, Patricia Kaishian, André De Kesel, and Meredith Blackwell</i>	263
Phylogenetic Advances in Leotiomycetes, an Understudied Clade of Taxonomically and Ecologically Diverse Fungi <i>C Alisha Quandt and Danny Haelewaters</i>	284
Pezizomycetes <i>Donald H Pfister and Rosanne Healy</i>	295
Outline of Basidiomycota <i>Mao-Qiang He and Rui-Lin Zhao</i>	310
<i>Cantharellales</i> Gäum <i>Ibai Olariaga</i>	320
Boletales <i>Matteo Gelardi</i>	329
Functional Traits of Stipitate Basidiomycetes <i>Hans Halbwachs and Claus Bässler</i>	361
Fossil Ascomycota and Basidiomycota, With Notes on Fossil Lichens and Nematophytes <i>Hans Halbwachs, Carla J Harper, and Michael Krings</i>	378
The Cultivation of Macrofungi <i>Simone Di Piazza, Grazia Cecchi, Ester Rosa, and Mirca Zotti</i>	396
Macrofungi as Food <i>Peter E Mortimer, Eric Boa, Kevin D Hyde, and Huili Li</i>	405
Overview: Human Fungal Pathogens <i>Sirida Youngchim and Joshua D Nosanchuk</i>	418

Polyenes and Amphotericin B <i>Irene García-Barbazán and Óscar Zaragoza</i>	421
Azole Antifungal Drugs: Mode of Action and Resistance <i>Rocio Garcia-Rubio, Maria C Monteiro, and Emilia Mellado</i>	427
Echinocandins <i>Alexander J Lepak and David R Andes</i>	438
Allylamines, Morpholine Derivatives, Fluoropyrimidines, and Griseofulvin <i>Kelly Ishida and Vinícius de Moraes Barroso</i>	449
New Targets for the Development of Antifungal Agents <i>Cristina de Castro Spadari, Taissa Vila, Vinícius de Moraes Barroso, and Kelly Ishida</i>	456
Immunotherapy of Fungal Infections <i>Kausik Datta and Liise-Anne Pirofski</i>	468
Diagnosis of Fungal Infections <i>María J Buitrago and Clara Valero</i>	498
Commensal to Pathogen Transition of <i>Candida albicans</i> <i>Ilse D Jacobsen, Maria J Niemiec, Mario Kapitan, and Melanie Polke</i>	507
<i>Candida psilosis</i> Complex <i>Tibor M Nemeth, Attila Gacser, and Joshua D Nosanchuk</i>	526
<i>Candida auris</i> : A New, Threatening Yeast <i>Javier Pemán and Alba Ruiz-Gaitán</i>	544
Immune Response to <i>Candida albicans</i> Infection <i>Alberto Yáñez, Celia Murciano, M Luisa Gil, and Daniel Gozalbo</i>	556
Infections by <i>Cryptococcus</i> species <i>Suëlen A Rossi and Óscar Zaragoza</i>	576
Epidemiology of Infections Caused by Molds <i>Jennifer M Cuellar-Rodriguez and Luis Ostrosky-Zeichner</i>	584
Diseases Caused by <i>Aspergillus fumigatus</i> <i>Rocio Garcia-Rubio and Laura Alcazar-Fuoli</i>	591
Mucormycosis <i>Priya Uppuluri, Abdullah Alqarihi, and Ashraf S Ibrahim</i>	600
Epidemiology of Dimorphic Fungi <i>Ana CO Souza and Carlos P Taborda</i>	613
Histoplasma <i>Joshua D Nosanchuk, Daniel Zamith-Miranda, and Allan J Guimarães</i>	624
Coccidioidomycosis: The Valley Fever <i>Hazael Hernandez and Luis R Martinez</i>	629
<i>Blastomyces</i> and Blastomycosis <i>Bruce S Klein, Joseph A McBride, and Gregory M Gauthier</i>	638
Paracoccidioidomycosis <i>Carlos P Taborda, Luiz R Travassos, and Gil Benard</i>	654
Sporotrichosis <i>Rodrigo Almeida-Paes, Maria C Gutierrez-Galhardo, and Rosely M Zancopé-Oliveira</i>	676
Advances in Genomics Research of <i>Pneumocystis</i> Species <i>Aleksey Porollo and Melanie T Cushion</i>	687

Subcutaneous Fungal Infections <i>Dayvison FS Freitas, Priscila M de Macedo, Maria C Gutierrez-Galhardo, and Fábio Francesconi</i>	695
Superficial Infections of the Skin and Nails <i>Priscila M de Macedo and Dayvison FS Freitas</i>	707
Genitourinary Fungal Infections (Other Than Vaginal Candidiasis) <i>Sutthichai Sae-Tia and Bettina C Fries</i>	719
Oropharyngeal and Vulvovaginal Candidiasis <i>Margaret E McCort</i>	726
Fungal Infections of Human Mammary Gland During Lactation <i>Katarzyna Łubiech and Magdalena Twarużek</i>	730
Fungal Infections of the Central Nervous System <i>Haroldo C de Oliveira, Rafael F Castelli, Diogo Kuczera, Taiane N Souza, Caroline M Marcos, Liliana Scorzoni, Leonardo Nimrichter, and Marcio L Rodrigues</i>	736
Fungal Cardiac Infections <i>Sichen Liu and Joshua D Nosanchuk</i>	749
Fungal Ophthalmological Infections <i>Daniel J Polla and Joann J Kang</i>	757
AIDS-Related Mycoses <i>Tihana Bicanic, Clare Logan, Beatriz L Gomez, Thuy Le, and Sean Wasserman</i>	763
Fungal Infections in Transplant Recipients <i>Jeremy S Nel, Anne Lachiewicz, and David Van Duin</i>	781
Fungal Infections in Cancer Patients <i>Bruno P Granwehr and Dimitrios P Kontoyiannis</i>	792
Fungal Infections in the Setting of Biological Therapies (in the Non-Transplant Host) <i>Michail S Lionakis</i>	803
Uncommon Yeasts and Molds Causing Human Disease <i>Christopher J Shoff and John R Perfect</i>	813
Fungal Infections in Children <i>Sandra Guerguis, Philip Lee, and David L Goldman</i>	835

LIST OF CONTRIBUTORS FOR VOLUME 1

- Mostafa M. Abo Elsoud
National Research Centre, Giza, Egypt
- Laura Alcazar-Fuoli
Carlos III Health Institute, Madrid, Spain
- Rodrigo Almeida-Paes
Oswaldo Cruz Foundation, Rio de Janeiro, Brazil
- R. Alonso-Monge
Complutense University of Madrid, Madrid, Spain
- Abdullah Alqarihi
*The Lundquist Institute, Harbor–University of California
Los Angeles Medical Centre, Torrance, CA, United
States*
- Claudio Altomare
National Research Council, Bari, Italy
- Antonella Amicucci
University of Urbino, Urbino, Italy
- David R. Andes
University of Wisconsin, Madison, WI, United States
- Maria Aragona
*Council for Agricultural Research and Analysis of the
Agricultural Economy, Research Centre for Plant
Protection and Certification, Rome, Italy*
- Marzia Beccaccioli
Sapienza University of Rome, Rome, Italy
- Gil Benard
University of Sao Paulo, Sao Paulo, Brazil
- Joan W. Bennett
*Rutgers, The State University of New Jersey, New
Brunswick, NJ, United States*
- Somanon Bhattacharya
Stony Brook University, New York, United States
- Chitrabhanu S. Bhunjun
*Center of Excellence in Fungal Research, Mae Fah
Luang University, Chiang Rai, Thailand and School of
Science, Mae Fah Luang University, Chiang Rai,
Thailand*
- Tihana Bicanic
*St George's University Hospital NHS Trust, St George's
University of London, London, United Kingdom and
MRC Centre for Medical Mycology, University of Exeter,
Exeter, United Kingdom*
- Meredith Blackwell
*Louisiana State University, Baton Rouge, LA, United
States and University of South Carolina, Columbia, SC,
United States*
- Eric Boa
*University of Aberdeen, Aberdeen, Scotland, United
Kingdom*
- María J. Buitrago
Carlos III Health Institute, Madrid, Spain
- Claus Bässler
*Department of Conservation Biology, Goethe University
Frankfurt, Frankfurt, Germany and Bavarian Forest
National Park, Grafenau, Germany*
- Rafael F. Castelli
Carlos Chagas Institute, Curitiba, Brazil
- Mafalda Cavalheiro
*iBB – Institute for Bioengineering and Biosciences,
Instituto Superior Técnico, University of Lisbon, Lisbon,
Portugal*
- Grazia Cecchi
University of Genoa, Genoa, Italy
- Shu Yih Chew
Universiti Putra Malaysia, Serdang, Selangor, Malaysia
- Walter Chitarra
*Research Centre for Viticulture and Enology, Council for
Agricultural Research and Economics, Conegliano, Italy;
Institute for Sustainable Plant Protection, National
Research Council, Torino, Italy; and National Research
Council, Torino, Italy*
- I. Correia
Complutense University of Madrid, Madrid, Spain
- Daniel Croll
University of Neuchâtel, Neuchâtel, Switzerland
- Jennifer M. Cuellar-Rodriguez
*National Institute of Allergy and Infectious Diseases,
Bethesda, MD, United States*
- Melanie T. Cushion
*University of Cincinnati College of Medicine,
Cincinnati, OH, United States and The Veterans Affairs
Medical Center, Cincinnati, OH, United States*
- Dong-Qin Dai
*Center for Yunnan Plateau Biological Resources
Protection and Utilization, College of Biological Resource*

*and Food Engineering, Qujing Normal University,
Qujing, Yunnan, PR China*

Kausik Datta
*Johns Hopkins University School of Medicine, Baltimore,
MD, United States*

Cristina de Castro Spadari
University of São Paulo, São Paulo, Brazil

André De Kesel
Meise Botanic Garden, Meise, Belgium

Priscila M. de Macedo
*Evandro Chagas National Institute of Infectious
Diseases, Oswaldo Cruz Foundation, Rio de Janeiro,
Brazil*

Vinicius de Moraes Barroso
University of São Paulo, São Paulo, Brazil

Francesca Degola
University of Parma, Parma, Italy

Simone Di Piazza
University of Genoa, Genoa, Italy

Sebastien Duplessis
University of Lorraine, Nancy, Champenoux, France

Weiguo Fang
*College of Life Science, Zhejiang University, Hangzhou,
China*

Nuria Ferrol
*Department of Soil Microbiology and Symbiotic Systems,
Zaidín Experimental Station, Spanish National Research
Council (EEZ-CSIC), Granada, Spain*

Fábio Francesconi
*Tropical Medicine Foundation Dr. Heitor Vieira
Dourado and Federal University of Amazonas, Manaus,
Brazil*

Dayvison F.S. Freitas
*Evandro Chagas National Institute of Infectious
Diseases, Oswaldo Cruz Foundation, Rio de Janeiro,
Brazil*

Bettina C. Fries
*Stony Brook University, Stony Brook, NY, United States
and Northport Veterans Affairs Medical Center,
Northport, NY, United States*

Attila Gacser
University of Szeged, Szeged, Hungary

Antonia Gallo
National Research Council, Bari, Italy

Mónica Galocha
*iBB – Institute for Bioengineering and Biosciences,
Instituto Superior Técnico, University of Lisbon, Lisbon,
Portugal*

Rocio Garcia-Rubio
*Hackensack Meridian Health Center for Discovery and
Innovation, Nutley, NJ, United States and Carlos III
Health Institute, Madrid, Spain*

Irene García-Barbazán
*National Center for Microbiology, Carlos III Health
Institute, Madrid, Spain*

Laura C. García-Carnero
University of Guanajuato, Guanajuato, Mexico

Gregory M. Gauthier
University of Wisconsin, Madison, WI, United States

Matteo Gelardi
Anguillara Sabazia, Italy

Stefano Ghignone
*Institute for Sustainable Plant Protection – National
Research Council of Italy, Turin, Italy*

M. Luisa Gil
University of Valencia, València, Spain

David L. Goldman
*Albert Einstein College of Medicine, Bronx, New York,
NY, United States*

Beatriz L. Gomez
*School of Medicine and Health Sciences, Universidad del
Rosario, Bogota, Colombia*

Manuela Gómez-Gaviria
University of Guanajuato, Guanajuato, Mexico

Michał Gorczak
University of Warsaw, Warszawa, Poland

Daniel Gozalbo
University of Valencia, València, Spain

Bruno P. Granwehr
*The University of Texas MD Anderson Cancer Center,
Houston, TX, United States*

Alessandro Grottoli
*Council for Agricultural Research and Analysis of the
Agricultural Economy, Research Centre for Plant
Protection and Certification, Rome, Italy*

Sandra Guerguis
*Albert Einstein College of Medicine, Bronx, New York,
NY, United States*

Allan J. Guimarães
Fluminense Federal University, Rio de Janeiro, Brazil

Maria C. Gutierrez-Galhardo
Evandro Chagas National Institute of Infectious Diseases, Oswaldo Cruz Foundation, Rio de Janeiro, Brazil

Santiago Gutiérrez
University of León, Ponferrada, Spain

Yitzhak Hadar
Hebrew University, Jerusalem, Israel

Anita Haegi
Council for Agricultural Research and Analysis of the Agricultural Economy, Research Centre for Plant Protection and Certification, Rome, Italy

Danny Haelewaters
Purdue University, West Lafayette, IN, United States; Ghent University, Ghent, Belgium; Universidad Autónoma de Chiriquí, David, Panama; and University of South Bohemia, České Budějovice, Czech Republic

Hans Halbwachs
Department of Conservation Biology, Goethe University Frankfurt, Frankfurt, Germany and Bavarian Forest National Park, Grafenau, Germany

Carla J. Harper
Trinity College Dublin, Dublin, Ireland; Bavarian State Collection for Paleontology and Geology, Munich, Germany; and University of Kansas, Lawrence, KS, United States

Mao-Qiang He
State Key Laboratory of Mycology, Institute of Microbiology, Chinese Academy of Sciences, Beijing, People's Republic of China

Rosanne Healy
University of Florida, Gainesville, FL, United States

Hazael Hernandez
Texas Tech University Health Sciences Center, Lubbock, TX, United States

Kevin D. Hyde
Center of Excellence in Fungal Research, Mae Fah Luang University, Chiang Rai, Thailand and Mushroom Research Foundation, Chiang Mai, Thailand

Ashraf S. Ibrahim
The Lundquist Institute, Harbor–University of California Los Angeles Medical Centre, Torrance, CA, United States and University of California Los Angeles, Los Angeles, CA, United States

Alessandro Infantino
Council for Agricultural Research and Analysis of the Agricultural Economy, Research Centre for Plant Protection and Certification, Rome, Italy

Kelly Ishida
University of São Paulo, São Paulo, Brazil

Ilse D. Jacobsen
Hans Knöll Institute, Jena, Germany

Patricia Kaishian
Purdue University, West Lafayette, IN, United States and State University of New York, Syracuse, NY, United States

Joann J. Kang
Albert Einstein College of Medicine, Bronx, NY, United States

Mario Kapitan
Hans Knöll Institute, Jena, Germany

Magnus Karlsson
Swedish University of Agricultural Sciences, Uppsala, Sweden

Bruce S. Klein
University of Wisconsin, Madison, WI, United States

Dimitrios P. Kontoyiannis
The University of Texas MD Anderson Cancer Center, Houston, TX, United States

Michael Krings
Bavarian State Collection for Paleontology and Geology, Munich, Germany; Ludwig-Maximilians-University Munich, Munich, Germany; and University of Kansas, Lawrence, KS, United States

Diogo Kuczera
Carlos Chagas Institute, Curitiba, Brazil

Anne Lachiewicz
University of North Carolina, Chapel Hill, NC, United States

Luisa Lanfranco
University of Turin, Turin, Italy

Thuy Le
Duke University School of Medicine, Durham, NC, United States and Oxford University Clinical Research Unit, Ho Chi Minh city, Vietnam

Philip Lee
Albert Einstein College of Medicine, Bronx, New York, NY, United States

Alexander J. Lepak
University of Wisconsin, Madison, WI, United States

Huili Li
Kunming Institute of Botany, Chinese Academy of Sciences, Kunming, Yunnan, China and Centre for Mountain Futures, Kunming Institute of Botany, Kunming, Yunnan, China

Michail S. Lionakis
*National Institute of Allergy and Infectious Diseases,
National Institutes of Health, United States*

Sichen Liu
*Albert Einstein College of Medicine, New York City, NY,
United States*

Clare Logan
*St George's University Hospital NHS Trust, St George's
University of London, London, United Kingdom*

Antonio F. Logrieco
National Research Council, Bari, Italy

Cécile Lorrain
*Max Planck Institute for Evolutionary Biology, Plön,
Germany; Christian-Albrechts University of Kiel, Kiel,
Germany; and University of Lorraine, Nancy,
Champenoux, France*

Katarzyna Łubiech
Kazimierz Wielki University, Bydgoszcz, Poland

Caroline M. Marcos
São Paulo State University, Araraquara, Brazil

Andrea Martinez
*Rutgers, The State University of New Jersey, New
Brunswick, NJ, United States*

Luis R. Martinez
University of Florida, Gainesville, FL, United States

Joseph A. McBride
University of Wisconsin, Madison, WI, United States

Margaret E. McCort
*Albert Einstein College of Medicine, Bronx, NY, United
States*

Emilia Mellado
*Mycology Reference Laboratory, National Centre for
Microbiology, Instituto de Salud Carlos III (ISCIII),
Majadahonda, Madrid, Spain*

Maria C. Monteiro
*Mycology Reference Laboratory, National Centre for
Microbiology, Instituto de Salud Carlos III (ISCIII),
Majadahonda, Madrid, Spain*

Héctor M. Mora-Montes
University of Guanajuato, Guanajuato, Mexico

Vinícius Morais Barroso
University of São Paulo, São Paulo, Brazil

Peter E. Mortimer
*Kunming Institute of Botany, Chinese Academy of
Sciences, Kunming, Yunnan, China and Centre for
Mountain Futures, Kunming Institute of Botany,
Kunming, Yunnan, China*

Celia Murciano
University of Valencia, Valencia, Spain

Jeremy S. Nel
University of the Witwatersrand, Johannesburg, South Africa

Tibor M. Nemeth
University of Szeged, Szeged, Hungary

Luca Nerva
*Institute for Sustainable Plant Protection, National
Research Council, Torino, Italy; National Research
Council, Torino, Italy; and Research Centre for
Viticulture and Enology, Council for Agricultural
Research and Economics, Conegliano, Italy*

Maria J. Niemiec
Hans Knöll Institute, Jena, Germany

Leonardo Nimrichter
Federal University of Rio de Janeiro, Rio de Janeiro, Brazil

Joshua D. Nosanchuk
*Albert Einstein College of Medicine, Bronx, NY, United
States*

Ursula Oggenfuss
University of Neuchâtel, Neuchâtel, Switzerland

Ibai Olariaga
Rey Juan Carlos University, Móstoles, Madrid, Spain

Haroldo C de Oliveira
Carlos Chagas Institute, Curitiba, Brazil

Luis Ostrosky-Zeichner
*Memorial Hermann Texas Medical Center, Houston,
TX, United States*

Pedro Pais
*iBB – Institute for Bioengineering and Biosciences,
Instituto Superior Técnico, University of Lisbon, Lisbon,
Portugal*

Javier Pemán
*Health Research Institute Hospital La Fe, Valencia,
Spain and Hospital University and Polytechnic La Fe,
Valencia, Spain*

John R. Perfect
*Duke University Health System, Durham, NC, United
States*

Preface	xxvii

VOLUME 1

Next Generation Sequencing: Transcriptomics <i>Fabiano Sillo</i>	1
The Cell Wall of Medically Relevant Yeasts and Molds <i>Manuela Gómez-Gaviria, Laura C García-Carnero, Alma K Tamez-Castrellón, and Héctor M Mora-Montes</i>	12
The Fungal Chitinases <i>Georgios Tzelepis and Magnus Karlsson</i>	23
GTPases in Hyphal Growth <i>Bianca Ranocchi and Antonella Amicucci</i>	32
Membrane Transporters, an Overview of the Arbuscular Mycorrhizal Fungal Transportome <i>Nuria Ferrol</i>	44
Fungal Secondary Metabolism <i>Francesco Vinale, Krishnapillai Sivasithamparam, Susanne Zeilinger, and Santiago Gutiérrez</i>	54
Mycotoxins and Mycotoxigenic Fungi: Risk and Management. A Challenge for Future Global Food Safety and Security <i>Claudio Altomare, Antonio F Logrieco, and Antonia Gallo</i>	64
RNA Interference in Fungi <i>Alessandro Silvestri and Luisa Lanfranco</i>	94
The MAP Kinase Network As the Nervous System of Fungi <i>I Correia, D Prieto, R Alonso-Monge, J Pla, and E Román</i>	102
Communication With Plants <i>Marzia Beccaccioli, Valeria Scala, and Massimo Reverberi</i>	114
Genome Evolution of Fungal Plant Pathogens <i>Maria Aragona, Alessandro Infantino, Maria Teresa Valente, Alessandro Grottoli, and Anita Haegi</i>	123
Mycoviruses: A Hidden World Within Fungi <i>Luca Nerva and Walter Chitarra</i>	134
Transposable Elements in Fungi: Coevolution With the Host Genome Shapes, Genome Architecture, Plasticity and Adaptation <i>Cécile Lorrain, Ursula Oggenfuss, Daniel Croll, Sebastien Duplessis, and Eva Stukenbrock</i>	142
Aspergilli, More Than Just Fungi: Shaping the Last Decades of Model Systems <i>Francesca Degola</i>	156
Proteomics in Mycorrhizal and Plant Pathogenic Fungi <i>Federico Vita and Stefano Ghignone</i>	164

Host-Induced Stress Response in Human Pathogenic Fungi <i>Romeu Viana, Pedro Pais, Mafalda Cavalheiro, Mónica Galocha, and Miguel C Teixeira</i>	182
Biodegradation of Aromatic Toxic Pollutants by White Rot Fungi <i>Yitzhak Hadar</i>	197
Fungal Chitin and Chitosan <i>Mostafa M Abo Elsoud</i>	205
Chitin Synthases in Fungi <i>Weiguo Fang</i>	218
Glucose Metabolism and Use of Alternative Carbon Sources in Medically-Important Fungi <i>Shu Yih Chew and Leslie Thian Lung Than</i>	220
Ergosterol Synthesis <i>Somanon Bhattacharya</i>	230
Fungal Volatile Organic Compounds <i>Andrea Martinez and Joan W Bennett</i>	239

EDITOR BIOGRAPHIES

Editor In Chief

Dr Óscar Zaragoza received his degree in Biology in 1995, and in 1996 he started his scientific career, which has been focused on microscopic fungi. He started his PhD under the supervision of Dr Juana María Gancedo (Biomedical Research Institute, CSIC, Madrid, Spain) in 1996. He obtained his PhD in 2000, and in his thesis, he studied catabolite repression in the yeast *Saccharomyces cerevisiae*. During this period, and under the supervision of Dr Carlos Gancedo, Dr Zaragoza started working with human pathogenic fungi, using *Candida albicans* as model.

In 2001 he started his postdoctoral training in the laboratory of Dr Arturo Casadevall (Albert Einstein College of Medicine, New York), who is one of the most recognized scientists in the field of Clinical Mycology. During this period, he focused his research on human pathogenic fungi, and in particular, on *Cryptococcus neoformans*, which has a significant prevalence among HIV+ patients. In 2006, he returned to Spain, and began his work

as Principal Investigator at the Mycology Reference Laboratory of the National Centre for Microbiology of the National Health Institute Carlos III (Madrid, Spain), directed by Dr Rodríguez-Tudela and Dr Cuenca-Estrella.

Dr Zaragoza's group main interest is the investigation of human fungal pathogens. These microorganisms affect mainly immunosuppressed patients, and they are associated with high mortality rates and a significant increase in the economic cost of patient treatment. In the last decade, he has directed two main research lines. One is focused on the mechanisms of fungal adaptation to the host, using the pathogen *C. neoformans* as model. In addition, the group is interested in the investigation of antifungal agents (action mechanisms and resistance). Dr Zaragoza is currently working at the Mycology Reference of the National Centre for Microbiology of the National Health Institute Carlos III, where he also supervises different tasks aimed to support the National Health System (identification and antifungal susceptibility of clinical isolates).

His research has authored more than 80 publications in some of the most important international journals of the field (*PLOS Pathogens*, *mBio*, *Infection and Immunity*, *mBio*, *Cellular Microbiology*, *Antimicrobial Agents and Chemotherapy*, among others), and several chapters in specialized books. Dr Zaragoza is also member of the editorial boards of *PLOS ONE*, *BMC Microbiology*, *Frontiers in Microbiology* (*Fungi and their development*) and *Mycopathologia*.

Honorary Editor

Arturo Casadevall, M.D., Ph.D., is a Bloomberg Distinguished Professor and Alfred and Jill Summer Chair of the Molecular Microbiology and Immunology at Johns Hopkins School of Public Health. He received his M.D. and Ph.D. degrees from New York University. He completed his internship/residency in internal medicine at Bellevue Hospital and specialized in Infectious Diseases at the Albert Einstein College of Medicine. The author of over 800 papers, books and chapters, his major research interests are in fungal pathogenesis and the mechanisms of antibody action. He is editor-in-chief of *mBio*, Deputy Editor of the *Journal of Clinical Investigation* and serves on several editorial boards. He has received numerous honors including election to the American Society for Clinical Investigation, American Academy of Physicians, American Academy of Microbiology, Fellow of the American Academy for the Advancement of Science, American Academy of Arts and Sciences and the National Academy of Medicine.

Section Editors

Raffaella Maria Balestrini. Biologist, PhD in Fungal Biology and Biotechnology. With CNR since 1998, Raffaella is currently a Research Director at CNR-IPSP. She has expertise on studies aimed to highlight the cellular and molecular bases of plant-soil microorganism interactions, mainly focusing on cell wall changes and nutritional exchanges. She mainly contributed to elucidate different aspects related to the interface creation and, by applying a laser micro-dissection (LMD) approach, she contributed to obtain new knowledge on the cell-specificity in arbuscular mycorrhizal (AM) roots. Thanks to the participation at diverse international consortia, she has contributed to highlight the genome features of different mycorrhizal fungi. Current research interests mainly address crop responses to environmental stresses and the role of root-associated microorganisms (e.g., mycorrhizal fungi) in improving tolerance. Scientific activities have been carried out within national and international projects including EU projects. Member of the editorial board for different scientific journals and she reviewed several project proposals for different national and international Institutions. She is member of diverse Editorial Boards of international peer-reviewed scientific journals. She has published over 100 papers in peer-reviewed indexed journals and many book chapters.

Miia R. Mäkelä is Principal Investigator and Adjunct Professor at the Department of Microbiology, University of Helsinki, Finland. Her main research interest is to understand fungal plant biomass conversion and degradation at the molecular level and apply this knowledge in biotechnology.

She obtained her PhD in Microbiology from the Faculty of Agriculture and Forestry, University of Helsinki. Her postdoctoral projects addressed various aspects of fungal lignocellulose degradation, including genome mining and characterization of novel enzymes for plant biomass conversion and valorization. During her position at Westerdijk Fungal Biodiversity Institute, The Netherlands, she focused on regulation of plant biomass conversion and metabolic engineering in ascomycete fungi. She received the prestigious Academy of Finland Research Fellowship position in 2017, which allowed her to develop a research line on the basidiomycete regulatory systems controlling plant biomass conversion process. Functional genomics and post-genomic approaches as well as genome editing are integral to her research.

She has (co-)authored over 100 peer-reviewed publications and has been a guest-editor for two special issues of the journal *Fungal Genetics and Biology*. She is currently an editorial board member for *Biotechnology Letters*, and an associate editor for *Frontiers in Fungal Biology* and *Frontiers in Microbiology*.

Josh Nosanchuk, MD is Professor of Medicine (Infectious Diseases) and Microbiology & Immunology as well as Senior Associate Dean for Medical Education at Albert Einstein College of Medicine in New York City. In his Dean position, Dr Nosanchuk strives to integrate basic, clinical and health system science across the curriculum of the medical school. Dr Nosanchuk's laboratory focuses on pathogenic fungi and novel therapeutics. Major pathogenic fungi studied include *Histoplasma capsulatum*, *Candida parapsilosis*, *C. auris*, *C. albicans*, and *Cryptococcus neoformans*. In particular, the laboratory investigates 1) how antibody can modify disease outcomes, 2) the role of melanin production on pathogenesis, and 3) the effects of extracellular release of vesicles from fungi, which contain numerous products associated with virulence. Novel therapeutics developed in the Nosanchuk laboratory include melanin-binding antibodies that have been used in a clinical trial for melanoma and pre-clinical compounds such as nitric oxide-releasing nanoparticles and siRNA targeting fidgetin-like 2, a microtubule severing enzyme that regulates wound healing.

Carla Viegas is a full Professor at Lisbon School of Health Technology, Director of the Occupational Health Master's course and researcher at H&TRC- Health & Technology Research Center from ESTeSL-IPL, NOVA National School of Public Health, Public Health Research Centre, Universidade NOVA de Lisboa and Comprehensive Health Research Center (CHRC). She is graduated in Environmental Health from Lisbon School of Health Technology – Polytechnic Institute of Lisbon has a Masters degree in Safety and Ergonomics from Lisbon University and PhD in Occupational and Environmental Health from New University of Lisbon. Her major field of study is occupational and environmental mycology leading and participating in several national and international projects about both areas of expertise. Special interests are occupational exposure to fungi in highly contaminated settings and complementarity of culture based- methods and molecular tools to assess fungal contamination. Additionally, she has expertise in sampling campaigns performed in different occupational environments using wide sampling and analyses approach to assess multiple microbiologic agents. Carla has authored has several publications/communications in the referred areas of specialization.

Alfredo Vizzini is a biologist with over 30 years' experience in Systematic Mycology. He graduated with a PhD in Biology and Biotechnology of fungi from the Department of Plant Biology of Torino, Italy. He is now an Associate Professor of Systematic Botany at the University of Torino (Department of Life Sciences and Systems Biology) where he teaches biodiversity of fungi and terrestrial plants. His research interests focus on mushroom taxonomy, especially agaricoid and boletoid species, using morphological and molecular approaches.

He is the author of over 200 publications on peer-reviewed international journals. Alfredo is currently associate/section editor of the journals *Ascomycete.org*, *Biodiversity Data Journal*, *Bulletin of Environmental and Life Sciences*, *Italian Botanist*, *MycoKeys*, *Mycosphere*, *Phytotaxa*, *Studies in Fungi*, *Taxonomy*, and a curator of the webpages *Basidiomycota* (<https://basidio.org/>), and *Faces of Fungi* (<https://www.facesoffungi.org/>).

Ronald P. de Vries. Group Leader Fungal Physiology at Westerdijk Fungal Biodiversity Institute (The Netherlands) and Professor in Fungal Molecular Physiology at Utrecht University (The Netherlands).

His research addresses the conversion of biomass (plant and marine) by fungi, focusing on the extracellular enzymes, the intracellular metabolic pathways and the transcriptional regulators that control these processes, as well as the application of fungi for the biobased economy. It contains a strong (post-)genomic component combined with modern and established experimental methodologies, such as genome editing, enzymology, metabolic engineering and physiology.

He graduated at Wageningen University (The Netherlands) and spent some time there and at Institut Pasteur (Paris, France) as a postdoc, after which he moved to Utrecht University as a postdoc and senior scientist, before taking up his current position. He obtained the prestigious Dutch VIDI (2005) and VICI (2013) grants and became an honorary member of the Hungarian Microbiological Society in 2017. He is a visiting professor at University of Helsinki (Finland) and a member of the fungal advisory board of the Joint Genome Institute, USA.

PREFACE

Fungi are organisms that have a profound significance in multiple processes of great importance for our daily life. But, apart from their influence in human affairs, fungi are fascinating organisms to study in themselves. They comprise both macroscopic and microscopic organisms, and it is estimated that there are somewhere between one and five million species of fungi. Fungi are found in most of ecosystems and are in constant contact with multiple other organisms, being involved in many commensal, symbiotic and parasitic interactions.

From a biological point of view, fungi are heterotrophic eukaryotic organisms that have a cell wall that contains chitin and several other polysaccharides (glucan, galactomannan, etc). They can reproduce by both sexual and asexual cycles. Despite the great variation among fungal morphology (macroscopic and microscopic), genetic tools reveal close relationships from an evolutionary point of view, and are closer to animals than to plants. But still, the Fungal kingdom contains a great variability in structure, shape, colour, reproduction and biology.

Most readers are already familiar with macroscopic fungi (mushrooms). Their colours and shape could be considered as one of the beautiful creations of nature, and many people look forward to those seasons of the year when they can enjoy viewing them in fields and forests. But in addition, macroscopic fungi have been enigmatic organisms for centuries. Some of them are edible, others poisonous or hallucinogenic, and still others have medical properties. Nowadays, they have multiple applications, not only as a delicious food source, but also in biotechnology, and there is a great evidence of their role in geochemical balance in the environment.

A major part of mycology involves microscopic fungi, which are divided in two main classes: yeasts and filamentous fungi (or moulds). And although invisible to the eyes, their biology and effects are also fascinating. In fact, we could express the importance of microscopic fungi by remembering one of the most famous quotes from the “The little Prince”, when the Fox revealed that the essential things in life are invisible to the eyes. When Antoine de Saint-Exupéry wrote this quote, he did not refer to microscopic fungi, but when we consider all the effects that they have on our world, we could certainly consider them as essential. How would the world be today without fungi? We will never know, but the fact that fungi are found in most ecosystems and establish interactions with all kind of living organisms indicate that they have played a role in evolution to select and shape our current world and way of living. Even in the case of humans, fungi have influenced the evolution of our immune systems, microbiota and other aspects such as body temperature. For thousands of years, we have taken advantage of fungal biology to produce cheese, wine, bread, beer and many other products. Paradoxically, we have not understood the basis of their action until relatively recently in our history, towards the end of XIXth century, and nowadays they are a powerful tool in today’s biotechnology. Fungi triggered a revolution in the medicine when Alexander Flemming found that they can be the source of antibiotics. Since the discovery of penicillin from the fungus *Penicillium notatum*, the search for many other compounds with biological activities produced by any kind of microorganism has been continuous and successful. Today fungi produce numerous important drugs including antimicrobial drugs and statins. In addition, fungi are used as microscopic factories to produce many compounds of interest or acquire new metabolic functions that provide multiple biotechnological applications.

Research in microscopic fungi has been classically promoted by their important role in biotechnology. This interest began during the XXth century as the industry developed and some species became important model organisms (*Saccharomyces cerevisiae*, *Schizosaccharomyces pombe* or *Neurospora crassa*, and *Aspergillus nidulans*), which allowed studies that led to the unravelling of key aspects in metabolism, genetics, cell cycle regulation, circadian cycles and many others are process. Even the first eukaryotic microorganism that was fully sequenced was the yeast *S. cerevisiae*, which highlight the importance of these microorganisms in research.

Despite their innumerable beneficial effects, the interaction of fungi with other living organism such as plants and animals can also result in deleterious outcomes and disease. We could explain the role of fungi as potential pathogens by revealing the secret that the letter “F” hides in the name Fungi, since they can be considered as either Friends or Foes. In the case of humans, microscopic fungi can cause many different diseases. Some of these pathogenic fungi live as inoffensive commensal in our body, but in some cases, depending on multiple factors, mainly related to our immune system, they can produce damage and disease. In some way, we could envision them as the main character from the classic written by Robert L. Stevenson, so these fungi could resemble to the kind and nice Dr. Jekyll that sometimes turns into the hideous and evil Mr. Hyde. In other cases, fungi that cause disease are acquired from the environment and they do not belong to our microbiota. This poses the challenge of how environmental changes (global warming, release of antimicrobial, use of antifungals, environmental interactions, etc) affect the virulence of the fungi that we constantly acquire from external sources. Most of fungal diseases are superficial and non-life threatening, but they can cause great discomfort. The incidence of these types of fungal diseases, such as infections of the skin (i.e., athletes foot), eye and mucosae such as the vagina (mainly vaginal candidiasis) or oral cavity is enormous, reaching around one hundred millions of people per year. In addition, some fungal species can be the causative agents of invasive disease, mainly among immunocompromised patients. As historical curiosities, the first cases of HIV+ was originally diagnosed with invasive fungal diseases. And even more anecdotic, fungi were in some moment linked to the mythical “Tutankhamun’s Curse” and related to the deaths of some of the discoverers of the tomb of the young Pharaoh. Nowadays, it is estimated that around 1.5 million people die every year due to fungal pathogens, a number that is unacceptably high. Moreover, beyond humans, fungi can also cause devastating plagues in the environment in animals and plants. As examples of their negative effects, the economic impact of fungi as crops contaminants is estimated in billions of dollars every year. And among animals, many fungi are common causes of disease

in multiple species, both vertebrates and invertebrates, and there are some species of amphibians have been driven to extinction by fungal diseases. In the United States the so called 'white nose syndrome' fungal disease threaten to drive several bat species to extinction.

In conclusion, the biology of fungi and their multiple effects in our world justified the organization of this Encyclopaedia, which has been possible to develop thanks to the dedicated work of the editors that have organized the five sections in which this work is organized: **Dr. Carla Viegas** (Lisbon School of Health Technology/Polytechnic Institute of Lisbon, Portugal, editor of Environmental Mycology), **Dr. Alfredo Vizzini** (University of Torino, Italy, editor of Macroscopic fungi), **Dr. Raffaella Ballestrini** (Fungal Biology), **Dr. Miia R. Mäkelä** (University of Helsinki, Finland) and **Dr. Ronald P de Vries** (Westerdijk Fungal Biodiversity Institute/Utrecht University, both editors of the Fungal Biotechnology section) and **Dr. Josh Nosanchuk** (Einstein College of Medicine, New York, editor of Medical Mycology). This work has been also possible due to the engagement of a large number of authors who are leading experts in their respective fields. We would like to stress that the development of this project took place during COVID19 pandemic, which has all our lives. We are aware of how difficult it has been for many authors to continue with their regular work (academia, research, health assistance, etc) with the restrictions caused by the pandemic. We are sure that for all of them, participation in this Encyclopaedia required a great deal of extra effort, and for this, and we are very grateful for their dedication and engagement in this enterprise. We also acknowledge and thank the Elsevier staff for their support and their assistance with such a challenging project. We warmly thank all the people involved in the completion of this Encyclopaedia, and we are proud that the final result provides a nice and comprehensive work on one of the most exciting topics in Biology.

The Rise of NGS Transcriptomics in Fungi

Genomics and its applications are some of the most advanced areas of current biological research. However, the genome sequencing represents just the first step toward a broad knowledge of an organism. The integration of functional, structural and cellular approaches that, all together, form the so-called *post-genomic* activities, is necessary for the deeply understanding of the role and the network of genes/proteins, and to the assignment of functions to the whole gene dataset discovered into organisms. Transcriptomics is one of the most developed fields in this current *post-genomic* era. By mirroring the differential gene expression during development and different phases of organisms life cycle, as well as during their responses to biotic and abiotic factors, the transcriptome constitutes the dynamic link between the static genome of an organism, a tissue or a cell, and its phenotype, at a specific time point (Meijueiro *et al.*, 2014; Stark *et al.*, 2019). In fact, morphogenetic changes of organisms might often depend on corresponding changes of activity of large numbers of genes. Several studies on single transcripts were carried out many years before any transcriptomics approaches were available. Traditional techniques included cDNA Amplified Fragment Length Polymorphisms (cDNA-AFLP), low-throughput Sanger sequencing of random transcripts from complementary DNA (cDNA) libraries [namely, expressed sequence tags (ESTs)], and PCR-based techniques, i.e. retro-transcriptase quantitative PCR (RT-qPCR) (Bhadauria *et al.*, 2007; Lowe *et al.*, 2017). Nevertheless, only after the development and the improvement of higher-throughput techniques it was possible to investigate how an organism transcriptome as a whole is finely regulated.

Fungal transcriptomics is a rising field which has gained more and more attention in the last two decades. The first fungal transcriptome, based on serial analysis of gene expression (SAGE), was released in 1997 for yeast (Velculescu *et al.*, 1997), and after that, thanks to the development and the availability of modern large-scale molecular tools, an exponential increasing number of fungal transcriptomes was published (Nowrousian, 2013; Meijueiro *et al.*, 2014). Currently, even if some other recent promising techniques has been proven to be useful in transcriptomics i.e., high throughput-SuperSAGE (HT-SuperSAGE) (Soanes *et al.*, 2012), the two most popular large-scale transcriptomic approaches applied in fungi remained microarrays (Nowrousian, 2007) and RNA sequencing (RNA-seq) (Wang *et al.*, 2010b). Microarrays refers to a collection of thousands of oligonucleotide spots, defined as probes, attached to a solid surface, which can hybridize a cDNA, defined as target, under high-stringency conditions (Schulze and Downward, 2001). The cDNA sequences, each of them representing a single transcript, are labeled and hybridize to the corresponding gene sequences on the array, and relative abundance of cDNA in the target is quantified by fluorescence detection and quantification (Schulze and Downward, 2001). This technology allowed for the first time the simultaneous analysis of thousands of transcripts. Pioneering fungal microarray studies were performed in yeast more than 20 years ago (DeRisi *et al.*, 1997; Lashkari *et al.*, 1997). Microarrays have been produced for several species of filamentous fungi, mainly by using PCR amplicons from EST libraries (Breakspear and Momany, 2007). The application of microarray technology to decipher transcriptomic profiles of fungi subjected to different conditions has proven to be useful for extending the knowledge on how fungi face with their surrounding environment. For example, *Cryphonectria parasitica* cDNA microarrays were used to monitor the changes in transcriptional profile when infected by a hypovirus (Allen *et al.*, 2003). A significant reprogramming of the *C. parasitica* transcriptome was observed and differentially expressed genes (DEGs) related to stress responses, carbon metabolism, and transcriptional regulation were detected (Allen *et al.*, 2003). Another classical example is represented by microarrays for *Aspergillus nidulans*, fabricated by using PCR products from a EST libraries generated during conidial germination, and used to assess the transcriptomic response of the fungus to different nutrient sources (Sims *et al.*, 2004). In the symbiotic Ascomycete *Tuber melanosporum*, microarrays allowed to track the transcriptomic changes occurring in its life cycle, in particular during the shift from free living mycelium to the formation of ectomycorrhizas and fruit bodies (Martin *et al.*, 2010).

However, it should be noted that microarray-based technology can be affected by some important limitations. First, for the customization of arrays, a reference genome sequence or a comprehensive set of EST sequences must be available, and second, non-specific or repeated cDNA sequences with high similarity hybridization to targets might strongly affect the dynamic range of the recorded signal (Lowe *et al.*, 2017). Moreover, not characterized transcripts (e.g., non-coding transcripts) and RNA species missing in EST libraries or in genome annotations cannot be detected by using this technology which is based on the availability of well-known sequences (Lowe *et al.*, 2017).

Currently, the emergence and the democratization of high throughput next-generation sequencing (NGS) techniques as substitute to Sanger sequencing for large-scale genomic analysis provided an opportunity to further explore and understand the differential gene expression at an exceptional resolution (Marconi *et al.*, 2014). In contrast to traditional Sanger sequencing, NGS allowed high throughput parallel sequencing of over millions of DNA nucleotides from multiple samples at reduced cost and time (Metzker, 2010). International sequencing activities, such as the ongoing “1000-fungal genomes” project (see “Relevant Websites section”) of the U.S. Department of Energy (DOE) Joint Genome Institute (JGI) (Grigoriev *et al.*, 2014), are aimed at increasing the dimension of fungal genome sequence databases by covering all fungal taxonomic units through sequence characterization of the most representative isolates. Remarkably, for almost all genome projects currently finished or in progress, a related large scale gene expression dataset is provided (Kuske *et al.*, 2015). Dedicated databases containing manually annotated fungal transcript sequences (e.g., see “Relevant Websites section”; Stajich *et al.*, 2012) are also in ongoing development.

Fig. 1 Results of a search on Scopus database (www.scopus.com) with the terms “microarray AND fungi” and “RNA-seq AND fungi”. Number of publications and years were reported.

In this line, RNA-Seq refers to the sequencing, through NGS, of transcripts converted into cDNA sequences, in which abundance is directly proportional to the number of counts from each transcript (Stark *et al.*, 2019). Compared to microarrays, RNA-seq does not require a priori knowledge of the genome sequence and this method can potentially be used for the detection of quantification of each RNA species present in samples, including non-coding or uncharacterized RNAs. RNA-seq overcomes microarray technology because of its intrinsic potential to discover transcript variants, i.e., transcripts showing SNPs and mutations (Stark *et al.*, 2019). Comparative transcriptomics analyses using RNA-seq provided high accurate determination of quantitative expression levels, the identification of tissue-specific transcript splicing variants and isoforms, and the detection of small and large non-coding RNAs involved in gene expression regulation (Stark *et al.*, 2019). For all these reasons, RNA-seq has become the gold standard for whole-transcriptome gene expression quantification (Fig. 1).

Transcriptomics Through RNA-Seq

The first step of a RNA-seq, as for microarray, includes the isolation of RNA from the samples, either from single fungal isolates and from environmental matrices. Commercial kits available for plant so far have started to be optimized also for fungal materials, and some protocols for extraction of high-quality RNA with sequencing purposes have been published (Patyshakuliyeva *et al.*, 2014; Cortés-Maldonado *et al.*, 2020). This step is crucial since fungal cells, in some cases even more than plant cells, may contain nasty chemicals such as melanin and phenolic compounds as well as high levels of polysaccharides which can interfere with the downstream analysis, especially those PCR-based. In addition, the yield of fungal RNA in some samples such as plant or food samples is often very low (Argumedo-Delira *et al.*, 2008). Optimal starting amount of RNA for RNA-seq may range from 100 ng to 1000 ng, but there are kits available for ultra-low RNA input such as 10 pg–10 ng (Tariq *et al.*, 2011). Once RNA is isolated, purified and its quality is checked, several NGS platforms are available. One of the first NGS technology serving transcriptomic research was pyrosequencing, a method involving sequencing-by-synthesis followed by detection of pyrophosphate release during the activity of DNA polymerase through chemiluminescent enzymes, such as luciferases (Ronaghi, 2001). Pyrosequencing was licensed by 454 Life Sciences and allowed to obtain sequences of approximately 500 bp in size, but, as becoming noncompetitive for costs, the platform was discontinued in 2013. Currently, the two most popular and established NGS platforms used for RNA-seq in fungi are manufactured by Illumina (MiSeq and HiSeq) and Ion Torrent (Lahens *et al.*, 2017). The two platforms mainly differ for the basic sequencing technologies: while for Illumina amplified individual library DNA molecules were spotted on a solid surface and a fluorescence-based system for reading the bases in a nucleotide sequence is used (sequencing by synthesis), for Ion Torrent emulsion PCR libraries were used and detection is achieved by electronic sensors reading bases through the H^+ ion generated during nucleotide incorporation (Lahens *et al.*, 2017). Despite these NGS methods, defined as of second generation (the first included Sanger and Maxwell sequencing methods), proven to be powerful, they still retain some pitfalls, including the generation of short reads, i.e., ranging from 100 to 500 bp, which often might hinder the correct reconstruction of

Fig. 2 Example of visualization of aligned reads from a RNA-seq experiment in IGV. In (A), the chromosome 1 of *Aspergillus oryzae* isolate RIB40 is used as reference for the alignment and the pileup of reads embedded in a BAM file (SRR035603.bam) is showed. Coverage is represented as gray histogram on the top of the alignment. Red and blue arrow-blocks represent first strand and complementary paired-end reads, respectively. Black squared section is detailed in (B). In (B), structure of an intron is showed. The intronic region was not covered by reads from the transcript, and reads over-spanning the exon boundaries. A cyan line, representing the intron, links the two exons. Data for this figure were obtained from Nowrousian, M., 2013. Fungal gene expression levels do not display a common mode of distribution. BMC Research Notes 6, 55, and freely available in SRA database.

full-length transcripts (Lowe *et al.*, 2017). Recently, the so called third-generation/long-read methods appeared on the market. Third generation sequencing works by reading the nucleotide sequences at the single molecule level, in contrast to existing methods which require breaking DNA strands into small fragments and the subsequent amplification (Van Dijk *et al.*, 2014). In this scenario, the company PacBio developed the sequencing platform of single molecule real time sequencing (SMRT), where signals of fluorescent light emission from each nucleotide incorporated by a DNA polymerase bound to the bottom of a chip, characterized by an optical waveguide (zero-mode waveguide), were detected and sequences were resolved (Roberts *et al.*, 2013).

Whereas each platform requires specific protocols of library preparation and nucleotide detection, the second generation sequencing platforms are characterized by the need to prepare amplified sequencing libraries before proceeding to the sequencing of the amplified cDNA clones (Lowe *et al.*, 2017). A standard RNA-seq protocol shared among all platforms include the cDNA library preparation, which consists of nucleic acid fragmentation, cDNA synthesis from RNA using random or oligo (dT) primers, adapter ligation, fragment size selection, and PCR amplification. By contrast, third generation sequencing platforms does not need

the prior amplification of cDNA (Van Dijk *et al.*, 2014). It is worth noting that transcriptomics primary focus on coding RNA translated into proteins (mRNA) which typically represent the 2%–3% of the total RNA in a cell. Other RNA species are indeed present into cells, including ribosomal RNA (rRNA) and tRNA (which are approximately 95% of a cell), and non-coding RNA such as snRNA, siRNA, snoRNA and microRNA (Meijueiro *et al.*, 2014). Several strategies of enrichment of a specific RNA population can be used to trigger the transcriptomic analysis depending on the focus of the experiment. For example, mRNA is usually isolated and converted into cDNA by using reverse transcriptase and oligodT primers, whereas noncoding RNA species can be included in libraries by using immunoprecipitated RNA-binding proteins or by selectively ligating 3' and 5' adapters before the reverse transcription to cDNA (Lowe *et al.*, 2017).

Irespective of NGS platform used, transcripts deriving from RNA-seq are provided as short (less than 1.5K bp) sequences called *reads*, which can be aligned against a reference genome or *de novo* assembled into longer sequences when a reference genome is not available. However, Illumina and Ion Torrent platforms showed some differences in the generated data: for the first one all reads generated in a single run have the same lengths, while the read lengths of the second are variable (Lowe *et al.*, 2017). Paired end reads, i.e. reads from both ends of a fragment, can be also produced if the utilized NGS technology allowed it. Reads are typically provided as unsorted FASTQ files, a file format similar to FASTA but comprehensive of all the information about base-calling and sequence quality (Marconi *et al.*, 2014). Reads with low quality levels, i.e., low *phred* scores, or with sequence errors should be purged and sequences of vectors, adapters, tags, and tails that were added experimentally during the preparation of the libraries should be trimmed by specific bioinformatic tools (Kulski, 2016). Filtered reads are then assembled into longer sequences called *contigs* representing complete transcripts, their fragments or isoforms (Kulski, 2016). Presence of isoforms and alternative splicing in fungi has been indeed demonstrated so far (Grützmann *et al.*, 2014). Several bioinformatic tools are used to map the reads to genomic sequences, chromosomes and scaffolds. Compared to aligners of DNA sequences, RNA-seq mappers need to cope with intronic sequences which lead large gaps in the alignment. In fungi, the most established read mappers for this purpose include TopHat (Trapnell *et al.*, 2009), STAR (Dobin *et al.*, 2013), Trinity (Haas *et al.*, 2013), and MapSplice (Wang *et al.*, 2010a). Commercial softwares such as CLC Genomics Workbench (CLC bio, Cambridge, MA, USA) and Newbler (Roche 454 Life Science, Branford, CT, USA) are also available. A common output of the read alignment process is a sortable SAM (Sequence Alignment/Map) file or its compressed binary version BAM. Barcodes, read quality, amplicon tags and other information are embedded in this type of files (Li *et al.*, 2009). These format files can be used as input for the popular software SAMtools (Li *et al.*, 2009), which not only allows at calculating read coverage by performing read pileup on reference genome, but also can be useful for statistics and filtering purposes (Li *et al.*, 2009). Visualization of reads aligned to reference sequences can be achieved by using Integrate Genomic Viewer (IGV; Thorvaldsdóttir *et al.*, 2013) which has been developed as an open source easy to understand tool for the dealing of NGS data, with a fashionable graphical user interface (GUI) (Fig. 2).

On the other hand, as stated before, without the availability of a reference genome, reads need to be assembled into longer contigs through a *de novo* assembly process. This strategy is generally based on the generation of De Bruijn graphs, where overlapping sequences are represented as paths which overlap, in order to reconstruct the original transcript sequences (Grabherr *et al.*, 2011). This approach is also recommended as complementary analysis of reference-guided mapping, in order to identify transcripts missed by alignment processes and to correct errors that may occur during the annotation (Hölzer and Marz, 2019). *De novo* assembly of RNA-seq data is more challenging than *de novo* genome assembly because of difference on gene expression, potentially masking low expressed loci, and presence of splicing events, making the reconstruction of exons in genes in the assembly paths complicated (Hölzer and Marz, 2019). Several powerful free tools such as Trinity (Grabherr *et al.*, 2011), Oases (Schulz *et al.*, 2012), and SoapDeNovo (Xie *et al.*, 2014) were developed for *de novo* transcriptome reconstruction. Completeness of *de novo* assembly can be verified through different bioinformatic tools included in specific pipelines, such as BUSCO (Simão *et al.*, 2015). This step is pivotal because of presence of large gaps and missing transcripts are know to likely occurring during *de novo* assembly processes.

Transcript sequences deriving from RNA-seq analysis may allow to strongly improve *in silico* annotations of putative genes and gene structures, as well as to train bioinformatic tools like gene predictors (e.g., AUGUSTUS; Stanke *et al.*, 2006). Thanks to alignment of reads on the available genomes, assembled transcripts are utilized to detect intron-exon boundaries in predicted/annotated genes (Lowe *et al.*, 2017), thus reducing annotation errors. A study in *Laccaria bicolor* highlighted that approximately the 69% of predicted gene models deviated from the real transcript sequences derived by RNA-seq data (Larsen *et al.*, 2010). Characterization of transcriptome can be carried out through gene ontology (GO) mapping of sequences, via specific tools such as Blast2Go (Conesa *et al.*, 2005). Basically, the GO mapping processes result in the assignment of defined GO terms, which provide information on involved biological process, molecular functions and predicted cellular components, of annotated transcripts, in order to characterize them (Conesa *et al.*, 2005).

In addition to the *in silico* characterization of transcripts, the second main goal of RNA-seq experiments is to compare the expression level of genes in two or more different conditions. Quantification of gene expression can be achieved since the total number of reads per transcript is directly proportional to the level of a transcript multiplied by transcript length (Haas *et al.*, 2013). However, it is worth noting that transcripts with same expression levels may have different chance to be sequenced depending on their size. In order to reduce this issue, expression levels are frequently normalized by counting the number of reads or fragments per kilobase per million reads (RPKM and FPKM, respectively) (Mortazavi *et al.*, 2008). Normalizing data into RPKM also provide an indication of relative expression levels between transcripts in a single library or between two libraries showing different sequencing depth (Lowe *et al.*, 2017). Quantitative differences in transcriptional levels can be also normalized and calculated on raw read count through the use of dedicated tools, including the two R packages DESeq2 (Love *et al.*, 2014) and

Fig. 3 Example of visualization output of RNA-seq data. In (A), example of a heatmap. Gene expression pattern of each sample/condition is represented in columns, while rows represent expression of each specific gene. Transcript abundance is indicated by different color: high-expression (red), average expression (white) and low or no expression (blue), e.g., expression of Gene_20 is high on Condition_2, and very low in Condition_3. Genes with similar expression profiles can be hierarchical clustered. In (B), a volcano plot showing DEGs. Significant up-regulated genes were represented by red dots ($\log_2\text{fold change} > 2$, $p\text{-value} < 0.05$), while down regulated genes were represented by blue dots ($\log_2\text{fold change} < -2$, $p\text{-value} < 0.05$). Black dots represent genes slightly regulated and/or not significantly expressed. Both $p\text{-value}$ and fold changes were $\log_2$ -transformed, as usually carried out for this type of data. Data for this figure were random generated.

edgeR (Robinson *et al.*, 2010), as well as the software Cuffdiff (Trapnell *et al.*, 2010), which test for differential expression using parametric approaches based on a negative binomial distribution model. The suite of tools Cufflinks embedded the algorithms for assembling transcripts, estimating their abundances, and assessing for differential expression (Trapnell *et al.*, 2012). The package *limma*, intended to be used for microarray data, has recently upgraded in order to perform differential gene expression analysis using RNA-seq data (Ritchie *et al.*, 2015). Recently, other softwares, e.g., Salmon, were developed to quantitatively and statistically assess DEGs by RNA-seq data (Patro *et al.*, 2017).

The outcomes of comparative analysis of differences in gene expression are often visualized as heatmaps, in which a color gradient for each gene represents its specific expression level in a determined condition/time/treatment (Fig. 3). Hierarchical clustering of genes showing similar patterns of expression may also be performed, allowing at fast tracking transcriptional changes at cluster level and at identifying gene co-expression patterns across different samples/conditions (Ben-Dor *et al.*, 1999; Lowe *et al.*, 2017). Volcano plots representing the whole set of DEGs are also commonly utilized to show a broad picture of the transcriptomic data (Fig. 3).

The raw sequence data from RNA-seq analysis are mostly submitted to dedicated sequence databases such as the NCBI Sequence Read Archive (SRA) database and the Gene Expression Omnibus and ArrayExpress, in order to obtain a database accession number useful for tracking data in publications (Shumway *et al.*, 2010). The number of accessions of RNA-seq studies in fungi in SRA database is increasing day by day (Fig. 4).

It should be mentioned that results from a large scale transcriptomic approach may be intrinsically prone to errors and attention should be focused during characterization of absolute gene expression levels. Several researchers agree that data from RNA-seq analysis have to be eventually validated using a target approach, such as the quantitative RT-PCR, by considering specific reference genes for normalization of expression, by following the Minimum Information for Publication of Quantitative Real-Time PCR Experiments (MIQE) guidelines, and by possibly using additional biological replicates (Bustin *et al.*, 2009; Fang and Cui, 2011).

NGS Transcriptomics to Identify Changes During Development and Growth Under Different Environmental Conditions

Experiments performed in fungi by using RNA-seq techniques allowed primarily to expand the knowledge on their basic biology, especially on shifts between the different phases of their life cycle. For instance, the cellular and molecular remodeling of mycelia to form complex reproductive structures such as fruit bodies have been studied in the light of changes in transcriptional landscapes. Several Basidiomycetes producing macroscopic fruit bodies were used as models to elucidating the mechanisms of the development of the reproductive structures. Through a comparative analysis of transcriptional patterns among six Agaricomycetes species, it has been demonstrated that, in fungi, fruit bodies development involves a major reprogramming of gene expression (Krizsán *et al.*, 2019). In *Schizophyllum commune*, for example, approximately 60% of total genes were expressed during specific developmental stage, including fruit body formation (Ohm *et al.*, 2010), while in *Auricularia polytricha*, about 9% of the total transcript catalogue were significantly differentially expressed during the shift from free living mycelium to fruit body

Fig. 4 Outcomes of a search on NCBI SRA database using the words “RNA-seq” and “organism: fungi” (search performed on March 2020). In (A), distribution of the main fungal phyla in the whole dataset of SRA accessions. Percentage (%) for each phylum is reported. In (B), (C), (D), (E) and (F) list of Ascomycota, Basidiomycota, Glomeromycota, Zygomycota, and Chitridiomycota species, respectively, with high number of accessions in NCBI SRA database.

(Zhou *et al.*, 2014). Common families of DEGs detected among Basidiomycetes during fruit body production are represented by genes coding for Carbohydrate Active Enzymes (CAZymes) affecting main components of the fungal cell wall, i.e., chitin and glucans, glycoside hydrolases (GH), hydrophobins, expansin-like proteins, and cerato-platanins (Krizsán *et al.*, 2019). The displacement of genes encoding cell wall related proteins seem to be required during the transition from simple to complex multicellular structures like macroscopic fruit bodies, which implied a dramatic cell wall remodeling. RNA-seq data also provide evidence of the crucial role in sporulation of several conserved key multicellularity-related genes including transcription factors, which are developmentally regulated in fruiting bodies (Pelkmans *et al.*, 2017; Krizsán *et al.*, 2019), and species-specific defense-related genes, suggesting that also chemical defense might be a function involved in a fruiting body production (Krizsán *et al.*, 2019). In *Morchella importuna*, the gene expression profile detected by RNA-seq analysis showed that carbohydrate catabolism and energy metabolism related pathways were finely regulated during fruit body formation, as well as genes encoding for heat shock proteins, thus suggesting a role of environmental temperature in sporulation (Hao *et al.*, 2019). From RNA-seq data, it was also observed that antisense transcripts may play a role in the formation of reproductive structures of *Coprinopsis cinerea* (Muraguchi *et al.*, 2015). A comparative large-scale analysis among three related smut species, i.e., *U. maydis* (common smut of corn), *Ustilago hordei* (covered smut of barley), and *Sporisorium reilianum* (head smut of corn), suggested that antisense RNAs could have a genome-wide influence on gene expression in smut fungi (Donaldson *et al.*, 2017). Antisense expression of genes appeared to have a role in growth and development of *Schizophyllum commune* (Ohm *et al.*, 2010), in *Aspergillus nidulans* (Sibthorp *et al.*, 2013), in the rice blast pathogen *Magnaporthe grisea* (Gowda *et al.*, 2006), and in *Neurospora crassa* (Arthanari *et al.*, 2014).

Sexual development transcriptional profiles were studied by high-throughput transcriptomic approach also in several Ascomycetes. Using *Botrytis cinerea* as a model system, whole transcriptome of apothecia was obtained and results allowed at inferring a possible priming role of gene involved in plant infection during fruit body generation (Rodenburg *et al.*, 2018). Comparative analysis of transcriptomic levels of orthologous gene repertoire between closely related species allowed at elucidating other ecological and evolutionary aspects of fungal development. For example, by coupling morphological characterization with RNA-seq analyses, it was possible to provide useful information on the ecological differences between two plant pathogenic fungi, *Fusarium verticillioides* and *F. graminearum* (Sikhakolli *et al.*, 2012). The comparison of the regulation of orthologous genes in a time-point experiment highlighted the different role of fruiting bodies in the ecology and epidemiology of the two pathogenic species (Sikhakolli *et al.*, 2012). A comparative RNA-seq analysis of several different truffle species (*Tuber* spp.) demonstrated that volatile organic compounds of their edible fruit bodies rely on the differential expression of a plethora of existing genes not strictly specific to *Tuber* species (Murat *et al.*,

2018). More recently, a transcriptomic profiling of the edible Ascomycete *Tuber magnatum* Pico (white truffle) has been obtained from fruit bodies collected under different environmental conditions, and a link between RNA-seq data and metabolomic profile has been performed (Vita *et al.*, 2020). Developmental transitions during the life cycle of *Tuber melanosporum*, i.e., free living mycelium, fruit body production and ectomycorrhizae, was also studied by RNA-seq (Tisserant *et al.*, 2011).

During adaptations to diverse environments, fungi seems to finely regulate different fractions of their transcriptomic pattern (Meijueiro *et al.*, 2014). For example, the genes and pathways associated to protein production in different culture media were identified in *A. nidulans* and *A. niger* by a RNA-seq analysis (Pullan *et al.*, 2014; Brown *et al.*, 2016). A RNA-seq study on the entomopathogenic fungus *Beauveria bassiana* suggested that the fungus adapted to different environmental niches by activating well-defined gene sets: for instance, when locust hind wings were used as substrate for growth, proteases were found to be induced, whereas the use of corn root exudates enhanced the expression of carbohydrate hydrolases (Xiao *et al.*, 2012). Colonization of wood by the brown rot agent *Postia placenta*, explored through a time course RNA-seq and coupled with enzymatic assays, allowed at detecting a unique fungal “pretreatment” strategy acting during the first phases of wood degradation, providing insights on a natural efficient conversion of woody plant materials into cellulosic compounds (Zhang *et al.*, 2016). In *Grosmannia clavigera*, RNA-seq data highlighted that the fungus can use products of detoxification of terpenoids as a carbon source, resulting in a transcriptional reprogramming of this species when subjected to environmental stresses (DiGuistini *et al.*, 2011).

NGS Transcriptomics to Decipher the Molecular Mechanism of Interactions With Other Organisms

Transcriptomic approaches based on NGS and aimed at dissecting the molecular mechanisms of interaction between fungi and other organisms has been successfully used in many different research fields. Given that the output of RNA-seq simultaneously comprises reads deriving from transcripts of both partners, and the comparison of these sequences against dedicated databases allow at distinguishing the origins of each transcript inside the RNA pool (Westermann *et al.*, 2012), this method was applied to study with high accuracy the pathways involved in the interaction dual experimental systems.

In the last years, large scale transcriptomics contributed to address important questions on human, animal and plant pathology, as well as on symbiosis between fungi and plants. A remarkable example is represented by a study on the opportunistic pathogenic yeast *Cryptococcus neoformans*, which causes human meningitis and it is responsible for thousands of deaths among immunodepressed people every years (Janbon *et al.*, 2014). By using RNA-seq, it was analyzed and compared the gene expression of two strains of *C. neoformans* collected from the cerebrospinal fluid of infected patients, and pathways that were crucial for the survival of *C. neoformans* in the central nervous system were identified. This allow at elucidating the genetic basis of the fungal disease (Chen *et al.*, 2014). Other important transcriptomic analysis performed on this basidiomycetous pathogenic yeast provided insights on *C. neoformans* response to stress, mating efficiency, and virulence (Janbon *et al.*, 2014; Yu *et al.*, 2020).

Plant disease were also studied from a fungal transcriptomic point of view. Transcriptomic profile of predicted secreted proteins strongly improved the ability to identify putative genes coding for small molecule selectively binding to plant proteins and regulating their biological activity, called effectors. It has been well documented that effectors play a key role during infection processes in compatible/incompatible interactions and in susceptibility/resistance to diseases, as well as in symbiosis (Alfano, 2009). Dual RNA-seq analysis on Norway spruce trees naturally infected by the forest pathogens *Heterobasidion* spp. revealed a specific repertoire of effector-like genes up-regulated during host colonization, in addition to genes encoding carbohydrate- and lignin-degrading enzymes (Kovalchuk *et al.*, 2019). The transcriptomic profile by NGS of the rice blast agent *Magnaporthe oryzae* during host infection allowed at identifying 240 transcripts encoding putative secreted proteins probably involved as effectors (Kawahara *et al.*, 2012). Up-regulation of genes encoding glycosyl hydrolases, cutinases and LysM domain-containing proteins were observed in the blast fungus, while expression of pathogenesis-related and phytoalexin biosynthetic genes was observed in rice (Kawahara *et al.*, 2012). Candidate effectors were discovered through dual RNA-seq in several important plant pathogens, e.g., *Cronartium ribicola* (Liu *et al.*, 2015), *Erysiphe pisi* (Gupta *et al.*, 2020), *Parastagonospora nodorum* (Jones *et al.*, 2019), *Puccinia striiformis* f. sp. *tritici* (Dobon *et al.*, 2016), and the number of new reported putative effector-like genes in different pathosystems is still rising.

Symbiosis between plants and fungi has been deeply studied through transcriptomic analysis. By using 454 pyrosequencing of transcripts isolated from the orchid mycorrhizal fungus *Tulasnella calospora* and its plant host *Serapias vomeracea*, an inventory of plant and fungal genes expressed in mycorrhizal protocorms was generated and the symbiotic process was characterized from both host and fungal sides (Balestrini *et al.*, 2014). The candidate effectors involved in the mutualistic symbiosis between the ectomycorrhizal fungus *Laccaria bicolor* and its hosts were also identified thanks to a large scale transcriptomic approach, and numerous small secreted proteins (SSPs) putatively involved in the establishment of the symbiosis were characterized (Martin *et al.*, 2008; Plett *et al.*, 2015). RNA-Seq data from fully formed ectomycorrhiza between *L. bicolor* and poplar roots were also used to predict the ectomycorrhizal metabolome (Larsen *et al.*, 2011). Large scale transcriptomics have been performed on other important ectomycorrhizal fungi, including *T. melanosporum* and *Paxillus involutus* (Kohler and Tisserant, 2014). Arbuscular mycorrhizal (AM) fungi has been also characterized through deep transcriptome sequencing. A RNA-Seq approach on the AM fungus *Rhizophagus irregularis* was performed, allowing at exploring the gene expression profile upon symbiosis with the plant *Medicago truncatula* (Tisserant *et al.*, 2013). About 4,7% of its genes were induced in colonized roots, and most of them were characterized as involved in signal transduction, energy production and conversion, secondary metabolism, transport and metabolism (Tisserant *et al.*, 2013). As for ectomycorrhizal fungi (Martin *et al.*, 2008), several genes coding for SSPs were found to be highly expressed during AM symbiosis interaction (Tisserant *et al.*, 2013).

Perspectives of NGS Transcriptomics in Fungi

Thanks of the exponential availability of specific protocols and reagents, in the last years NGS methods have been coupled to other novel molecular approaches in order to improve the resolution of analyses. A recent tool which has been proven to be useful when coupled to RNA-seq is laser microdissection (LM) technology. Laser microdissection is a powerful technology that allows the rapid isolation of selected cell populations from a section of heterogeneous tissues in a way conducive to the extraction of several cellular compounds, including nucleic acids, proteins and metabolites (Balestrini *et al.*, 2009). LM in fact combines the use of the microscope and the application of a manual guided (PC assisted) laser to separate different cytological components from specimen sections on a microscope slide. This technology was used in studies on mycorrhizal fungal symbioses in order to isolate cortical cells from roots of several plant species colonized by arbuscular mycorrhizal fungi in combination with gene expression target approaches (Balestrini and Fiorilli, 2020 for a review) and large scale transcriptomics (Gaude *et al.*, 2012) or from truffle/hazelnut ectomycorrhizae (Hacquard *et al.*, 2013), and in studies on plant pathogenic fungi in order to dissect the tissue-specific responses of plants to the infection (Hacquard *et al.*, 2010; Chandran *et al.*, 2010). Recently, one interesting study performed on the Ascomycete *Sordaria macrospora* has revealed the high potential of this tool for elucidating the various transcriptomic patterns of different fungal tissues (Teichert *et al.*, 2012). By selectively isolating RNA from protoperithecia and free living mycelia of *S. macrospora* through a LM approach, and by analyzing it with RNA-seq, significant difference in gene expression between the two components were detected (Teichert *et al.*, 2012).

Despite LM is useful for tissue-specific analysis, and tailored RNA isolation protocols are available for extraction of nucleic acid from chemically-treated samples like paraffine-embedded specimens (Takahashi *et al.*, 2010), a high number of cells are needed as starting biological material. In some cases, e.g., to investigate on differential expression of a spore population with different or similar genetic background, the RNA sequencing of a single cell [Single-cell RNA-seq (scRNA-seq; Saliba *et al.*, 2014)] is required. Several methods to isolate single cell from tissues and cell populations, i.e., multiparametric flow cytometry and sorting based on a fluorescence gating strategy, micromanipulation with a glass pipette, optical tweezers laser-based, were successfully used in several studies (Saliba *et al.*, 2014). In the last years, thanks to SMRT provided by third generation sequencing technology, scRNA-seq has started to be an established method for uncovering the individual transcriptomic complexity within populations of yeasts (Gasch *et al.*, 2017; Nadal-Ribelles *et al.*, 2019; Saint *et al.*, 2019). Results were promising and it is likely that this approach will be applied in future for other microorganisms, including filamentous fungi.

An emerging and promising field taking advantage by the rapid development of NGS tools and aimed at expanding the knowledge on the identification of multipartite metabolic interactions occurring between two or more organisms is represented by metatranscriptomics. Metabarcoding studies on DNA from environmental samples demonstrated without doubt to be very useful to study fungal community in the field. However, metabarcoding surveys may be biased by PCR amplification and not all species present in the samples have the same chance to be detected (Tedesoo *et al.*, 2015). Moreover, both dead and living organisms are detected by DNA sequencing, potentially masking the real structure of the living populations in some particular samples, e.g., in stool or soil samples, where contaminant DNA cannot be distinguished from DNA of the living microbial community (Marcelino *et al.*, 2019). The sequencing by RNA-seq of transcripts, representing the whole activity of genes of all organisms living in the samples, may circumvent this issue, helping researchers in ecological studies of complex fungal community (Kuske *et al.*, 2015; Marcelino *et al.*, 2019). In addition, as for dual RNA-seq, metatranscriptomics can allow to decipher the interactions among fungi and other organisms. Metatranscriptomics of some mycorrhizal communities have been recently performed, allowing a deeper understanding of the functional roles of these fungi in nature (Gonzalez *et al.*, 2018; Liao *et al.*, 2014). However, as for transcriptomics of a single organism, the interpretation of RNA-seq results from metatranscriptomics is still challenging, because of differences in transcript turnover rates and of limitations of using homology-based gene assignments during function prediction (Kuske *et al.*, 2015). The increased availability of annotated transcriptomes of fungal species in validated databases will aid to fill the missing information needed by future metatranscriptomics studies (Kuske *et al.*, 2015).

Conclusions

In the last years, thanks to NGS strategies, fungal transcriptomics has improved the understanding of how genomes are expressed during growth, development and under environmental stresses, what genes were involved in pathogenic and symbiotic interactions, and what is the role of different RNA species, such as non-coding RNA and antisense transcripts, in fungal life cycles. The growing availability of large-scale transcriptomics data allowed comparative analyses aimed at addressing important questions on functional, ecological and evolutionary aspects of fungi. Both small scale laboratories and big consortia have access to these NGS data, and thanks to the reduction of costs of NGS technology, they will be able to perform new transcriptomics studies in order to improve the databases and to strength the network between transcriptomics and other *omics* approaches. The new challenge for high throughput NGS transcriptomics, in fact, will be the growing request of computational resources for analyzing and storing big data coming from RNA-seq. Future improvement of sequencing technologies and bioinformatic tools will be pivotal to keep this positive trend, along with the proportional enhancement of bioinformatic facilities and sequence databases.

Introduction

Thus far, an estimated 1.5 million fungal species have been classified, and 300 out of there affect human beings (Fisher *et al.*, 2020). Fungal infections are acquiring relevance in the last years because most of them affect individuals already with serious underlying illnesses and are challenging to treat. The main risk factors for developing a fungal infection include anti-cancer, immunosuppressive and antibiotic therapies, solid organ and hematopoietic stem cell transplantations, HIV infection, diabetes mellitus, and the use of intravenous lines (Lanternier *et al.*, 2013). Moreover, the socio-economic and geo-ecological characteristics of a population can increase fungal disease risk factors, incidence, and prevalence (Bongomin *et al.*, 2017).

The fungal cell wall (CW) is a key player in the pathogenic process, being important in the fungal adhesion to the host, and contains pathogen-associated molecular patterns that can interact with the pattern recognition receptors of the host immune cells. The fungal CW is located above the plasma membrane, acts as a permeability barrier, contributes to cell shape and protection from osmotic and mechanic stresses, and is essential for cell integrity and viability (Díaz-Jiménez *et al.*, 2012). The fungal cell growth can be radial or polar, and this defines the final cell morphology of yeast and filamentous fungi, respectively. Molds grow by polarized and apical extension, forming filamentous and vegetative cells known as hyphae, whose continued growth forms the hyphal network name as mycelium. Thus, the hyphae's biological traits, including the CW structure and organization are closer to that found in molds.

The *Candida albicans* Cell Wall

Candida albicans is a dimorphic and opportunistic organism, and one of the leading etiological agents of nosocomial fungal infections (Brown *et al.*, 2012). The *C. albicans* CW is likely the most thoroughly studied fungal structure from medically relevant fungal species and will be used here as an example of CW composition, organization, and synthesis (Fig. 1). Its wall is a layered structure, with a homogeneous inner layer of about 100 nm and the outermost layer of about 180 nm and composed of proteins (Klis *et al.*, 2001). The main components of the CW are carbohydrates, contributing to 80%–90% of the CW dry weight (Díaz-Jiménez *et al.*, 2012; Mora-Montes *et al.*, 2009). These saccharides are chitin, β -1,3- and β -1,6-glucans, and mannose oligosaccharides (mannan) covalently associated with proteins (Mora-Montes *et al.*, 2009). Proteins and lipids contribute to about 6%–25% and 1%–7% of the CW dry weight (Chaffin *et al.*, 1998) (see Fig. 1).

Chitin and β -glucans are the main components of the wall inner layer, are covered by the outer layer components, except in the budding scars and the hypha primary septum (Perez-Garcia *et al.*, 2011), and are the wall skeleton that provides physical strength (Chaffin *et al.*, 1998). Chitin is a linear polymer and is arranged in an antiparallel fashion, associated with each other by hydrogen

Fig. 1 Representation of *C. albicans* cell wall. The inner layer of the cell wall (close to the cell membrane) is composed of antiparallel chitin chains, followed by β -1,3- and β -1,6-glucans. The outermost cell wall layer is composed of a thick mannoproteins layer that contains *N*-linked and *O*-linked mannans, and phospholipomannans.

bonds (Shepherd, 1987); while β -1,3-glucans are aligned and kept together by hydrogen bonds (Klis *et al.*, 2001). The β -1,6-glucans can be of variable lengths and distribution and act as molecular linkers between wall proteins and β -1,3-glucans and chitin (Klis *et al.*, 2001; Garcia-Rubio *et al.*, 2020). The outermost layer is composed of mannoproteins, which account for about 20%–30% of the total CW weight (Mora-Montes *et al.*, 2009), and may contain glycosylphosphatidylinositol (GPI) anchors that cross-link them to β -1,6-glucans (Garcia-Rubio *et al.*, 2020). They also contain O-linked and N-linked oligosaccharides attached to serine/threonine or asparagine residues, respectively (Fig. 1). The phospholipomannan is currently the main glycolipid characterized in this CW and contains β -1,2-oligomannosides linked to phytoceramide associated with phytosphingosine and hydroxy fatty acids (Trinel *et al.*, 2002).

Chitin Synthesis

Chitin is the second most abundant organic compound on earth, after cellulose, and is synthesized by a wide variety of organisms from different taxonomic groups, including pathogenic fungi (Merzendorfer, 2011). This is a homopolymer of N-acetylglucosamine (GlcNAc) that is linked by β -1,4- glycosidic bonds and folds on itself to form antiparallel chains of about twenty units. This arrangement allows compaction in strong microfibrils, more resistant than any other molecule in nature (Lenardon *et al.*, 2010).

A chitin proportion found in pathogenic fungi is deacetylated to chitosan by one or more chitin deacetylases (Klis *et al.*, 2006). In *C. albicans*, 5% of the chitin is deacetylated to chitosan, while in *Cryptococcus neoformans* more than 60% chitin is deacetylated (Baker *et al.*, 2007). Chitin synthesis is highly conserved in fungi and the process involves a defined number of enzymatic reactions that convert different sugars into a GlcNAc polymer. The sugar main source is glucose or its storage compounds -glycogen or trehalose (François and Parrou, 2001). The synthesis route is divided into three main reactions, the first leads to GlcNAc formation (Fig. 2), the second one follows a variant of the Leloir route that gives rise to uridine diphosphate (UDP)-GlcNAc (Fig. 2), and the last reaction involves chitin polymerization using UDP-GlcNAc as the activated sugar donor (Fig. 2). The first two reactions occur in the cytoplasm; while the third step takes place in specialized microdomains of the plasma membrane (Merzendorfer, 2011).

The presence of glutamine-fructose-6-phosphate amidotransferase, UDP-GlcNAc, and chitin synthase (CHS) are determinants for chitin synthesis. The CHS activity is specifically associated with chitin biosynthesis, and is divided into seven classes (I–VII); although the functional importance and presence of all these classes seem to be species-specific (Niño-Vega *et al.*, 2004) (Table 1). Class I and II enzymes produce only a small chitin fraction but are essential for the primary septum formation (Munro *et al.*, 2001). Class IV, V, and VII enzymes often produce considerable chitin amounts and share sequence homology; whereas class V and some class VII enzymes contain myosin-like domains (Niño-Vega *et al.*, 2004). Class III, V, VI, and VII enzymes have only been identified in filamentous fungi and are absent in *C. albicans* (Lenardon *et al.*, 2010) (Table 1). The multiplicity of CHS enzymes in various organisms suggests that they may have redundant functions in chitin synthesis.

The CHS are membrane proteins and the catalytic domain, which faces the cytoplasm, contains conserved saccharide- and nucleotide-binding sites (Merzendorfer, 2011). For this reason, nascent chitin chains must translocate through the plasma membrane before they assemble into microfibrils and are deposited on the cell surface. The chitin translocation process is thought to be a CHS intrinsic property that involves transmembrane segments of the C-terminal region (Lenardon *et al.*, 2010; Merzendorfer, 2011).

Fig. 2 Simplified chitin synthesis pathway in fungi, starting from glycogen. The acronyms in the figure refer to Glycogen phosphorylase (GP), phosphoglucomutase (PGM), glucose-6-phosphate isomerase (GPI), glutamine-fructose-6-phosphate amidotransferase (GFAT), glucosamine-6-phosphate-N-acetyltransferase (GNA1), phosphoacetylglucosamine mutase (AGM), UDP-N- GlcNAc pyrophosphorylase (UAP), chitin synthase (CHS) and chitinase.

Table 1 Classification of chitin synthases in fungi of medical interest

Organism	CHS classes							Function
	I	II	III	IV	V	VI	VII	
<i>C. albicans</i>	Chs2 Chs8	Chs1	–	Chs3	–	–	–	Chs1: primary septum synthesis Chs2 and Chs8: protection of the nascent cell wall during polarized growth Chs3: synthesizes the majority of chitin found in the cell wall as well as the chitin ring at division sites (Lenardon <i>et al.</i> , 2010)
<i>A. fumigatus</i>	ChsA	ChsB	ChsC ChsG	ChsF	CsmA	ChsD	CsmB	ChsA and ChsC: cell wall chitin compensation ChsB: function at polarized growth sites and forming septa during hyphal growth and conidia development CsmA and CsmB: these enzymes appear to localize themselves to sites of polarized cell wall expansion in an actin-dependent manner ChsD, ChsG, ChsF: unknown functions (Lenardon <i>et al.</i> , 2010)

Fig. 3 Schematic representation of the GLS complex, which is involved in the β -1,3-glucan synthesis. The FKS subunit catalyzes the elongation of growing β -glucan chains by the addition of UDP-glucose monomers. RHO is a GTP-dephosphorylase protein that regulates Fks1 and Fks2 by GDP. ROM is a cell wall-associated GDP-GTP exchange protein responsible for the GTP regeneration.

β -Glucans Synthesis

Most of the fungal β -glucans are made up of β -1,3-linked glucose units with varying amounts of β -1,6-linked branches. The β -1,3-glucans are the most important and abundant polysaccharides in the fungal CW, reaching around 65%–90% of total glucan content (Bowman and Free, 2006).

The initial step in the β -1,3-glucan synthesis is the cytoplasmic generation of the precursor UDP-glucose (UDP-Glc), used as a sugar donor by glucan synthases. In fungi, the GLS membrane protein complex (UDP-Glc:1,3- β -D-glucan 3- β -D-glucosyl-transferase), is in charge of catalyzing the reaction of β -1,3-glucan synthesis, using UDP-Glc as a substrate (Latgé, 2007). The elongation continues with the addition of UDP-Glc monomers at the non-reducing end of the growing glucan chain, and each new polymer is transported from the plasma membrane to the CW, through a channel of transmembrane domains. The GLS complex is composed of two subunits, a catalytic FKS unit and a regulatory RHO unit with guanosine triphosphatase activity (Beauvais *et al.*, 2001) (Fig. 3). The gene encoding for Fks1 of the FKS subunit is expressed in vegetative growth under optimal conditions; while FKS2 is induced by environmental stress or during sporulation. Various evidence indicates that Fks1 and Fks2 are the β -1,3-glucan synthase catalytic subunits (Dijkgraaf *et al.*, 2002; Nogami and Ohya, 2009).

It is known that RHO is a regulatory G protein, which fulfills the function of activating FKS by GTP dephosphorylation. A Rho1 post-translational modification is necessary for β -1,3-glucan synthesis, the C-terminal end of RHO-type GTPase is modified with a geranylgeraline group by the type I geranylgeranyltransferase enzyme, this modification is required for binding and activation of Fks1 (Ohya *et al.*, 1993; Nogami and Ohya, 2009). The ROM protein is also involved in this process, since allows GDP-GTP exchange in the wall and modulates RHO activity (Teparić and Mrsa, 2013). The cytosolic domains of FKS are responsible for

Table 2 Genes involved in the synthesis of β -1,3- and β -1,6-glucans in medically relevant fungi

<i>S. cerevisiae</i> gene ^a	<i>C. albicans</i>	<i>A. fumigatus</i>	Function
<i>KRE5</i>	<i>KRE5</i>	AFUA_2602360	UDP-glucose: glycoprotein glucosyltransferase, 1,6- β -D-glucan biosynthesis
<i>KRE6</i>	<i>KRE6</i>	BA78_1578	Essential β -1,6-glucan synthase subunit
<i>SKN1</i>	<i>SKN1</i>	BA78_1578	Protein with a role in β -1,6-glucan synthesis; probable <i>N</i> -glycosylated type II membrane protein
<i>KRE9</i>	<i>KRE9</i>	CDV57_05718	Protein of β -1,6-glucan biosynthesis; required for hyphal growth.
<i>KNH1</i>	<i>KNH1</i>	CDV57_05718	Protein involved in cell wall β -1,6-glucan synthesis, similar to Kre9
<i>KRE1</i>	<i>KRE1</i>	Not found	Cell wall glycoprotein; β -glucan synthesis
<i>RHO1</i>	<i>RHO1</i>	RHO1	Small GTPase of Rho family; regulates β -1,3-glucan synthesis activity
<i>FKS1</i>	<i>MEQ_00226</i>	FKS1	Essential β -1,3-glucan synthase subunit
<i>FKS2</i>	<i>GSL2</i>	FKSP	Protein similar to β -1,3-glucan synthase
<i>ROM2</i>	<i>ROM2</i>	ROM2	Putative GDP/GTP exchange factor

^aNotes: The synthesis of β -glucans has been extensively studied in the fungus *Saccharomyces cerevisiae* and the genes involved in this synthetic pathway are almost completely characterized. Therefore, using a blast analysis, taking as reference the *S. cerevisiae* genes, a search was carried out to determine the presence of these genes in the selected organisms. Gene nomenclature corresponds to accession codes of the GeneBank database (<https://www.ncbi.nlm.nih.gov/genbank/>).

catalysis, and therefore β -glucans synthesis takes place in the cytosol. Subsequently, the biomolecules go to the periplasmic space, where they are incorporated into the CW (Reverberi *et al.*, 2004; Bowman and Free, 2006). Other proteins, such as Pma1 have been found near the GLS complex, and this particular protein maintains an acidic environment in the CW closer to the membrane, which is important for glucan synthesis (Schimoler-O'Rourke *et al.*, 2003) (see Table 2).

The β -1,6-glucan synthesis is likely to occur on the cell surface, although the mechanism behind is not well dissected yet. The first step in its synthesis may involve an endoplasmic reticulum (ER) hypothetical protein acceptor, followed by the synthesis of polysaccharide chains and branching in later stages of the secretory pathway on the cell surface. However, the activity of the identified gene products remains unknown, so it is not clear how and to what extent they are involved in the synthesis of this polymer (Nogami and Ohya, 2009). Thus far, a cell surface β -1,6-glucan synthase has not been found, but several proteins of the Golgi apparatus and ER seem to be involved in this synthetic pathway in an unknown way (Shahinian and Bussey, 2000). The *KRE5*, *CWH41/GLS1*, *ROT2/GLS2*, and *CNE1* encode ER proteins that participate in the β -1,6-glucan synthesis (Shahinian *et al.*, 1998). In the case of Kre5, this has a similarity to UDP-glucose: glycoprotein glucosyltransferase and has been suggested that may play a role that indirectly contributes to glucan synthesis (Shahinian and Bussey, 2000) (see Table 2).

Glycoproteins Synthesis

The carbohydrate part of glycoproteins is known as glycans and are linked to the polypeptide backbone in a process known as protein glycosylation pathway. This posttranslational modification plays an important role in protein structure and function, affecting solubility, folding, stability, and intracellular trafficking (Helenius and Aebi, 2001). Some glycoproteins are covalently attached to the CW matrix and are known as "integral CW proteins", which often are produced as GPI-anchored proteins; while the "non-integral" proteins are weakly associated with the wall (Castillo *et al.*, 2008).

According to the glycan-binding site on the protein, there are two types of glycans, the *N*-linked and *O*-linked glycans. The *O*-linked glycans are short and simple oligosaccharides attached to the -OH group of serine or threonine side chain by an acyl bond, whereas the *N*-linked glycans are high-weight and highly branched oligosaccharides attached to asparagine residues within the sequon Asn-X-Ser/Thr (Mora-Montes *et al.*, 2009). The biosynthesis of both *N*-linked and *O*-linked glycans is a multi-step process that takes place in the ER and Golgi complex and involves glycosyltransferases, glycosidases, and other carbohydrate modifying enzymes (Mora-Montes *et al.*, 2009; Martinez-Duncker *et al.*, 2014).

The *N*-linked glycan synthesis begins with the assembly of a dolichol-linked oligosaccharide precursor, Glc₃Man₉GlcNAc₂, in the ER and its subsequent transfer in a co-translational mechanism by an oligosaccharyltransferase complex to the amide side chain of the asparagine of a nascent polypeptide (Martinez-Duncker *et al.*, 2014). Then, this precursor is processed to Glc₁Man₉GlcNAc₂, which is key for protein folding in the glycoprotein quality control mediated by the calnexin/calreticulin chaperones (Helenius and Aebi, 2001). Once the polypeptide is properly folded, the oligosaccharide is further processed to Man₈GlcNAc₂, which is directed to the Golgi complex for additional processing by mannosyltransferases, generating high mannose content *N*-linked glycans (Martinez-Duncker *et al.*, 2014). In *C. albicans*, the synthesis of an outer chain, and attachment to Man₈GlcNAc₂ takes place in the Golgi complex. This process begins with the α -1,6-mannosyltransferase Och1, which is responsible for adding one α -1,6-mannose unit to Man₈GlcNAc₂ (Martinez-Duncker *et al.*, 2014). Then, a chain containing 50 or more α -1,6-mannose residues is built on the initial mannose added by Och1, generating the outer chain backbone (Bates *et al.*, 2006). The enzymes involved in the backbone elongation are Van1, Anp1, Mnn9, Mnn10, and Mnn11 (Martinez-Duncker *et al.*, 2014). Then, lateral oligosaccharides containing α -1,2-mannose units branched the backbone and may be decorated with α -1,3-mannose or β -1,2-mannose units (Mora-Montes *et al.*, 2009). The enzymes required for the synthesis of this outer chain are listed in Table 3. In *C. neoformans*, the *N*-linked glycans contain xylomannan, having a long nucleus of α -1,6-mannoses with side chains consisting of α -1,2-mannoses ending in a xylose residue (Park *et al.*, 2013). In *Aspergillus fumigatus*, the outer chain has a different structure,

Table 3 Enzymes involved in the biosynthesis of fungal *N*-linked and *O*-linked glycans

Enzyme	<i>C. albicans</i>	<i>A. fumigatus</i>	Function
Och1	✓	✓	α -1,6-Mannosyltransferase; initiates <i>N</i> -glycan outer chain branch addition
Van1	✓	✓	Member of Mnn9 family of mannosyltransferases
Anp1	✓	✓	Putative Golgi-resident mannosyltransferase; member of Mnn9p family
Mnn9	✓	✓	Mannosyltransferase involved in the <i>N</i> -linked outer-chain mannan biosynthesis
Mnn10	✓	✓	α -1,6-Mannosyltransferase involved in biosynthesis and organization of cell wall polysaccharides
Mnn11	✓	✓	Role in protein <i>N</i> -linked glycosylation, protein glycosylation, and α -1,6-mannosyltransferase complex localization
Mnn2	✓	✓	α -1,2-Mannosyltransferase, required for normal cell wall mannan content
Mnn6	✓	✓	Role in protein glycosylation and Golgi apparatus localization
Mnn1	✓	✓	Putative α -1,3-mannosyltransferase; of the mannosyltransferase complex
Pmt1-Pmt6	✓	✓	Protein mannosyltransferase, member of the PMT family which includes Pmt1p, Pmt2p, Pmt4p, Pmt5p, and Pmt6p
Mnt1/Ktr1	✓	✓	α -1,2-Mannosyl transferase; predicted type II Golgi membrane protein
Mnt2	✓	✓	α -1,2-Mannosyl transferase, partially redundant with Mnt1
Mnt3	✓	✓	Mannosyltransferase

Notes: The presence or absence of the enzymes involved in the synthesis of *N*-linked and *O*-linked glycans in *Candida albicans* and *Aspergillus fumigatus* was determined. The presence of these enzymes was investigated in their respective genome databases (<http://www.candidagenome.org/>, <http://www.aspgd.org/>).

instead of a linear nucleus of α -1,6-mannose units there is a repeated tetrameric mannan composed of α -1,2-mannose- α -1,6-mannose- α -1,2-mannose- α -1,2-mannose with β -1,5-galactofuranose side chains (Henry *et al.*, 2016; Engel *et al.*, 2012) (see Table 3).

The *O*-linked glycosylation pathway also begins in the ER, where the Pmt1-Pmt6, a family of protein *O*-mannosyltransferases (PMT) takes a mannose unit from dolichol-phosphate-mannose and transfer it to an acceptor protein (Martinez-Duncker *et al.*, 2014; Mora-Montes *et al.*, 2009). Then, additional mannoses are added to the oligosaccharide by Golgi resident α -1,2-mannosyltransferases, generating a short chain of α -1,2-mannose residues that may contain up to seven mannose units (see Table 3) (Diaz-Jimenez *et al.*, 2012). *A. fumigatus* has *O*-linked mannogalactans, and there is evidence that the mannose chain has α -1,6- rather than α -1,2- bonds, although this fungus has Mnt1, the enzyme responsible for the production of α -1,2-mannan (Leitão *et al.*, 2003). In *C. albicans* and *C. neoformans*, Pmt2 is essential for cell viability (Willger *et al.*, 2009).

The *Candida albicans* Cell Wall Proteome

There are quantitative and qualitative differences in the *C. albicans* CW protein composition in both yeast and hyphae. The different proteins can be attached to the wall by a GPI anchor (Klis *et al.*, 2001; Satala *et al.*, 2020), these account for about 88% of all covalently linked proteins, and aspartyl proteinases, chitinases, glucanases, phospholipases, adhesins, and proteins for β -1,6-glucan biosynthesis are among the best GPI-containing wall proteins (Richard and Plaine, 2007). Moreover, it has been predicted that other 115 proteins with unknown functions are attached to the wall *via* a GPI anchor (Richard and Plaine, 2007).

Another type of wall proteins is released by extraction from intact cells with reducing agents, suggesting they are linked through disulfide bridges to other wall proteins (Klis *et al.*, 2001). Among these proteins, Eng1 (endo- β -1,3-glucanase), Gca1, Bgl2 (β -1,3-glucosyltransferase), Pdi, Pir1, MP65 (glucan metabolism), Sim1 (cell wall maintenance), Tos1, Pra1, and Iff2/Hyr3 have been identified (Caminero *et al.*, 2014). The last type of wall proteins are those linked directly to β -1,3-glucan through an alkali-sensitive linkage (without an interconnecting β -1,6-glucan moiety), the proteins have internal repeats and have been designated as Pir (Klis *et al.*, 2001).

The proteins mentioned above contain a signal sequence that allows transportation to the cell surface, *via* the conventional secretory pathway, but other proteins lacking that signal and non-covalently associated with the wall are also found (Satala *et al.*, 2020). In *C. albicans*, the presence of moonlight proteins in the CW has been described, and include Cdc25 (CDC25 cell division cycle), Aco1 (aconitate hydratase), Adh1 (alcohol dehydrogenase), Fba1 (fructose bisphosphate), Gap (glyceraldehyde-3-phosphate dehydrogenase), Icl1 (isocitrate lyase), Pdc11 (pyruvate decarboxylase), Act1 (actin), various Rpl (ribosomal proteins), Hsp90 and Hsp70 (heat shock protein), Tef1 (translation elongation factor eEF1 α -A chain) Atp1 (ATP synthase alpha subunit) Cit1 (citrate synthase), among others (Satala *et al.*, 2020). Some of these proteins have been described to have adhesion properties but others an unknown function in the CW (Satala *et al.*, 2020; Castillo *et al.*, 2008).

The Cell Wall Composition in Other *Candida* Species

Although the structure and composition of the *C. albicans* CW are well known, this is not the case for other *Candida* species, such as *Candida guilliermondii*, *Candida tropicalis*, *Candida krusei*, *Candida auris*, *Candida dubliniensis*, *Candida parapsilosis*, *Candida glabrata*, *Candida lusitanae*, and *Candida orthopsilosis*, mainly because it was thought that the *C. albicans* wall model could be applied to all these species (Navarro-Arias *et al.*, 2019).

Our group has determined the basic cell wall composition of *C. tropicalis*, *C. krusei*, *C. guilliermondii*, and *C. auris* (Navarro-Arias et al., 2019). The walls from the analyzed species had differences in the levels of chitin, glucan, mannan, and wall proteins, when compared to *C. albicans*: (1) *C. auris* has higher chitin levels; (2) *C. krusei* contains higher chitin levels and low mannan, glucans, and wall proteins contents; (3) *C. guilliermondii* possesses higher mannan levels; (4) and *C. tropicalis* and *C. albicans* have similar amounts of all the mentioned components. When the content of cell wall O-linked and N-linked mannans were also analyzed, it was observed that *C. guilliermondii* had increased levels of both mannans, while *C. krusei* showed lower levels when compared to *C. albicans* (Navarro-Arias et al., 2019). Two parameters associated with the mannan length, named phosphomannan content and wall porosity, were also evaluated: *C. albicans* and *C. auris* had similar phosphomannan levels; *C. tropicalis* and *C. guilliermondii* had a higher phosphomannan content, and *C. krusei* had a lower phosphomannan abundance (Navarro-Arias et al., 2019). The CW porosity was similar for *C. tropicalis*, *C. guilliermondii*, and *C. krusei*, but it was lower in *C. albicans* and *C. auris* (Navarro-Arias et al., 2019). Additionally, the experimental evidence suggested that both β -1,3-glucan and chitin are underneath the external mannan layer in all the analyzed species (Navarro-Arias et al., 2019).

Another study also reported the CW composition of *C. tropicalis*, *C. glabrata*, *C. parapsilosis*, and *C. guilliermondii* (Walker and Munro, 2020). They found that all of the species have similar glucan levels, except for *C. tropicalis* that had reduced glucan content, and *C. glabrata*, which had a higher content when compared to *C. albicans* (Walker and Munro, 2020). Mannan content was reduced in *C. glabrata*, *C. parapsilosis*, and *C. guilliermondii*; while chitin was in higher amounts in *C. tropicalis* but in lower levels in *C. glabrata* and *C. guilliermondii* (Walker and Munro, 2020).

The CW mannan structure from different *Candida* species has also been reported. In *C. krusei*, it was found that N-linked and O-linked mannans have a similar composition than that reported for *C. albicans* (Kuraoka et al., 2019). *C. tropicalis* and *C. albicans* were found to share certain mannan moieties; while *C. glabrata* mannans contain small branches with low α -mannan content and one or two α -1,2-linked mannose residues (Nguyen et al., 2018). In *C. parapsilosis*, the N-linked mannans are shorter and less complex than in *C. albicans*; and the O-linked mannans play a more important role during the interaction with the host, representing about half of the total wall mannan content (Perez-Garcia et al., 2016).

The *Aspergillus* Cell Wall

Aspergillus spp. encompass several environmental filamentous fungi considered as opportunistic, being *A. fumigatus* the main etiological agent of invasive aspergillosis, a disease linked with high mortality rates in immunocompromised patients (Garcia-Rubio et al., 2020). They possess two different morphotypes, conidia, and hyphae, and although the same polysaccharides are found in both, the CW organization is different (Beauvais et al., 2014). In general, the wall can be divided into an alkali-soluble fraction, which represents the wall outer layer, and an alkali-insoluble fraction, which is the inner layer. In the alkali-soluble fraction, linear α -1,3-glucans (92%), galactosaminogalactan (GAG) (7%), and galactomannan (3%) are found, while the insoluble fraction, which is thought to provide rigidity, is composed of galactomannan (8%), chitin (22%), chitosan (7%), β -1,3-glucans (51%) that can extend up to 1500 residues long, and a linear β -1,3/1,4-glucan (6%), component with an unknown role that has not been described in any other fungal species (Garcia-Rubio et al., 2020). The wall core is the β -1,3-glucan polymer, highly branched with β -1,6-linkages, to which chitin, chitosan, galactomannan, and β -1,3/1,4-glucan are covalently linked (Beauvais et al., 2014).

The β -1,3-glucan synthesis is essential for *A. fumigatus* viability, while defects in the chitin or galactomannan synthesis generate only sick cells with virulence attenuation (Bernard and Latgé, 2001; Schmalhorst et al., 2008).

In *A. fumigatus*, two types of wall-associated proteins can be found: (1) not glycosylated or glycosylated proteins without galactofuranose residues, which have been found also in the culture medium; (2) and N-linked and O-linked glycosylated GPI proteins containing galactofuranose, such as Gel2 and Ecm33, which are thought to be indispensable for the wall synthesis and vital for fungal growth (Jin, 2012). Gel2 belongs to a family of β -1,3-glucanotransferases, and its absence leads to slower growth, abnormal conidiogenesis, altered wall composition, and reduced virulence (Jin, 2012); while Ecm33 has an unknown function but participates in maintaining the correct wall architecture, and its disruption results in conidial separation defects, chitin accumulation, rapid conidia germination, and increased virulence (Jin, 2012; Romano et al., 2006). No proteins covalently bound to the *A. fumigatus* wall polysaccharides have been found, however, a proteomic analysis of wall-associated proteins described that an acid phosphatase is the major GPI-anchored protein strongly associated with β -1,3-glucan, although the presence of a covalent link was not established (Bernard et al., 2002).

The conidial CW is a two-layered structure that can be observed as a dense pigmented outer layer and as a translucent inner layer (Bernard and Latgé, 2001). It is known that this morphotype is covered by a superficial rodlet layer composed of the hydrophobic proteins RodA and RodB, known as hydrophobins (Beauvais et al., 2014; Bernard and Latgé, 2001), organized in an amyloid configuration making the wall waterproof (Latgé et al., 2017). There is a dihydroxy naphthalene (DHN) melanin layer underneath the hydrophobins, important for the CW structuration and stiffness (Latgé et al., 2017). These structures are required for conidia survival and dispersion into the air, and both overlap with the α -1,3-glucans (Latgé et al., 2017).

The rodlet layer also confers immunological inertness to the conidia by functioning as a masking mechanism to avoid the recognition of β -1,3-glucans by dectin-1 (Beauvais et al., 2014), and RodA was reported as the only essential protein for rodlet structure formation (Latgé et al., 2017). When RodA is missing from the surface, these morphotype is easily recognized by immune cells (Aimanianda et al., 2009). However, conidia without hydrophobins can still bind to the host cells *in vitro* and *in vivo*, with no changes in the virulence (Girardin et al., 1999).

Melanin presence in the wall helps conidia to counteract the effect of reactive oxygen species since albino conidia are more susceptible to these radicals and show a lower survival rate within phagocytic cells (Pihet *et al.*, 2009). It was demonstrated that melanin also plays an indirect role in the fungal pathogenesis, allowing the correct assembly of the wall layers of resting conidia (Pihet *et al.*, 2009). Analysis of albino mutants showed considerable changes in the conidial wall organization, with the loss of the outermost electron-dense layer, the absence of the rodlet layer, and a decrease in the cell electronegative charge (Pihet *et al.*, 2009).

The presence of sialic acid has also been reported in the conidial wall, being recognized by the *Sambucus nigra* agglutinin, a specific lectin that binds N-acetyl-neuraminic acid (Warwas *et al.*, 2007). High-performance liquid chromatography and mass spectrometry analyses confirmed the presence of this component in the conidia wall, and digestion with neuraminidase demonstrated that it helps the fungus to bind to the host extracellular matrix (Warwas *et al.*, 2007).

When conidia germinate due to water entrance and glycerol accumulation, the isodiametric growth gets replaced by polarized growth, causing the conidial wall rupture to form a germ tube with a wall that extends from the inner layer of the conidia. In consequence, several structures change in the cell, including the loss of the rodlet and melanin layers, which turn the hydrophobic surface of the conidium into hydrophilic; and the exposure of the β -glucans in the surface of the swollen conidia, which increases the surface adhesive properties (Latge *et al.*, 2017). The α -glucans exposed interact with each other, causing the swollen conidia aggregation (Latge *et al.*, 2017; Beauvais *et al.*, 2014).

In mycelia, around 90% of the CW is composed of polysaccharides, some of which are structurally and covalently bound to the β -1,3-glucan core; while others, such as α -1,3-glucan and GAG, fill up the pores between fibrillar polysaccharides (Latge *et al.*, 2017). After swelling, conidia germinate and develop into hyphae that can grow differently depending on the conditions, (1) as a network of agglutinated hydrophobic hyphae, under static and aerated conditions; (2) or as separate hyphae, under shaken liquid conditions. Electron microscopy analysis has shown that in the first case the wall looks like a single electron-translucent layer; while in the second case, it looks like a thin electron-dense layer with extracellular material covering the CW (Latge *et al.*, 2017).

In addition to the differences in the CW polysaccharides composition and organization in the two morphologies, these may also vary depending on the growth and nutritional conditions. For example, when the fungus is growing as a biofilm, the α -1,3-glucans are found on the surface of the mycelial wall, but when the growth is under shaken and submerged conditions, they are localized on the CW inner layer (Beauvais *et al.*, 2014). Also, *A. fumigatus* growth under limiting glucose concentrations results in a reduction of the β -1,3-glucan synthase activity, with a consequent reduction of CW β -1,3-glucan levels (Clavaud *et al.*, 2012). On the other hand, hypoxia is associated with an increment in β -1,3-glucans and chitin, and with the reduction of α -1,3-glucans (Shepardson *et al.*, 2013).

GAG is a heterogeneous linear polymer composed of α -1,4-linked galactose, N-acetyl-galactosamine, and galactopyranose, and is secreted by growing hyphae (Speth *et al.*, 2019). It is an important component during biofilm formation since it binds to the hyphal surface, creating a polysaccharide envelope that covers and protects the growing fungus, forming an extracellular matrix between hyphae (Speth *et al.*, 2019). When GAG deficient strains were evaluated in mouse models of invasive aspergillosis, they were incapable of forming biofilms and showed an attenuated virulence (Gravelat *et al.*, 2013; Speth *et al.*, 2019). Also, GAG is a major hypha adhesin, because mutants incapable of synthesizing this compound do not form biofilms, and exhibit a reduced adherence to pulmonary epithelial cells (Speth *et al.*, 2019; Gravelat *et al.*, 2013). Moreover, strains that overexpress this wall component exhibit an increased binding to the host cells and other surfaces (Neves *et al.*, 2017).

It is also known that GAG needs to be deacetylated by the enzyme Agd3, not only to bind to the hyphae but also to bind to other surfaces (Lee *et al.*, 2016). Agd3 mutants showed adhesion and virulence defects both *in vitro* and *in vivo* (Lee *et al.*, 2016). This wall component has been described in several *Aspergillus* species, including *A. fumigatus*, *Aspergillus nidulans*, *Aspergillus niger*, and *Aspergillus parasiticus* (Lee and Sheppard, 2016).

The Fungal Cell Wall and the Development of Antifungal Drugs

Since the CW has an essential role in maintaining cell integrity, this structure represents an attractive target for the development of antifungal drugs. Additionally, many wall components are not synthesized by the mammalian host, potentially reducing the collateral effects when developing a compound with antifungal properties. Besides the selection of the target, antifungals should ideally meet some criteria: (1) the activity of the antifungal must have a broad spectrum against yeast and filamentous fungi; (2) it should be fungicidal rather than fungistatic; (3) to be directed at a specific fungal target and to have no interference with host targets; (4) to have multiple delivery methods, particularly oral availability; and (5) to have minimal side effects or toxicities (Mazu *et al.*, 2016).

The chitin synthesis inhibitors act as analogs of the UDP-GlcNAc substrate for Chs. Among these inhibitors, we found polyoxins, which are closely related to nucleotide antibiotics that are produced by *Streptomyces cacaui* var *asoensis* (Endo *et al.*, 1970). The polyoxin D action mechanism is the competitive inhibition of Chs for UDP-GlcNAc (Endo *et al.*, 1970). The polyoxins are dipeptidyl or tripeptidyl nucleosides that are transported into the cell *via* a peptide transport system (Naider *et al.*, 1983). Nikkomycins X and Z are also competitive inhibitors of fungal Chs that are structurally similar to polyoxins. These compounds showed *in vivo* and *in vitro* antifungal activity against *Blastomyces dermatitidis* and *Coccidioides immitis* (Hector *et al.*, 1990). However, some fungi like *Candida* spp., *C. neoformans*, *Aspergillus* spp. have been reported to be resistant to nikkomycins (Hasim and Coleman, 2019).

Other Chs inhibitors are HWY-289, arthrichitin (activity against *Candida* spp., *Trichophyton* spp.), and FR-9000403 (Mazu *et al.*, 2016). A recent study found two benzothiazole compounds, described as IMB-D10 and IMB-F4, which inhibited Chs *in vitro*, reduced chitin levels in yeast cells, and inhibited the *S. cerevisiae* and *C. albicans* growth (Li *et al.*, 2019). Nikkomycin Z has shown to have a synergistic interaction with fluconazole and itraconazole against *C. albicans*, *C. parapsilosis*, *C. neoformans*, and *C. immitis*; while combined with itraconazole, Nikkomycin Z showed synergism against *A. fumigatus* and *Aspergillus flavus* (Li and Rinaldi, 1999).

Echinocandins are semisynthetic lipopeptides produced from fungal precursors: caspofungin from *Glarea lozoyonensis* pneumocandin B₀, anidulafungin from *A. nidulans* echinocandin B₀, and micafungin from *Coleophoma empedra* hexapeptide FR901370 (Eschenauer *et al.*, 2007). Echinocandins are hexapeptide with *N*-linked acyl fatty acid chains that intercalate in the cell membrane phospholipids (Lima *et al.*, 2019). The echinocandin's action mechanism is the noncompetitive inhibition of β -1,3-glucan synthase, which causes the decrease in the β -1,3- and β -1,6-glucan network, leading to a disordered and osmotically unstable CW and fungal death (Lima *et al.*, 2019). Echinocandins inhibit the Fsk subunit of the glucan synthase complex and mutations in this subunit lead to the resistance showed in some *Candida* species (Perlin, 2011).

Ibrexafungerp (SCY-078 formerly MK-3118) is a semisynthetic orally bioavailable enfumafungin derivative, structurally distinct from echinocandins. This compound is a potent inhibitor of glucan synthase, with activity even in echinocandin-resistant *Candida* strains (Pfaller *et al.*, 2017). Moreover, Ibrexafungerp exhibited antifungal activity against *C. auris* strains resistant to echinocandin and fluconazole (Arendrup *et al.*, 2020). In *C. glabrata*, spontaneous mutations in the β -1,3-glucan synthase *FKS* subunit showed partially overlapping but an independent binding sites for Ibrexafungerp and echinocandins (Jiménez-Ortigosa *et al.*, 2017).

The combination of nikkomycin Z and echinocandin (anidulafungin or micafungin) showed synergistic effects against *C. albicans* isolates and laboratory-derived echinocandin-resistant *fks* mutants (Cheung and Hui, 2017); while a similar observation was reported with echinocandin FK463 in *A. fumigatus* (Chiou *et al.*, 2001). The combination of different compounds with distinct targets may be a good solution for the arising problem of fungal resistance against antifungal drugs.

One of the proteins involved in GPI synthesis is Gwt1 (GPI-anchored wall protein transfer 1), an inositol acyltransferase that catalyzes inositol acylation (Lima *et al.*, 2019). The compound 1-[4-butylbenzyl]isoquinoline (BIQ) inhibits the expression of GPI-mannoproteins in both *S. cerevisiae* and *C. albicans*, resulting in growth inhibition (Tsukahara *et al.*, 2003). A missense mutation in *GWT1* suppressed the drug-induced growth-inhibitory phenotype, suggesting that the encoded protein is the target of this compound (Tsukahara *et al.*, 2003). A derivative compound from BIQ, E1210, has a broad-spectrum antifungal activity that also inhibits the fungal GPI biosynthesis and showed potent antifungal activity against *C. albicans*, *C. tropicalis*, *A. flavus*, *A. fumigatus*, and *Fusarium solani* (Hata *et al.*, 2011).

Another class of compounds are members of the pramidine family. Pramidicins appear to act by calcium-dependent complexing with the saccharide portion of cell surface mannoproteins, which leads to the perturbation of the cell membrane, leakage of intracellular contents and cell death (Gonzalez *et al.*, 1998). A derivative of paramedicine, BMS-181184, was proven to have *in vitro* antifungal activity against *Candida* spp., *C. neoformans*, *A. fumigatus*, dermatophytes, and *Sporothrix schenckii* but it had no activity against *A. niger*, *A. flavus*, *Malassezia furfur*, *Fusarium* spp., and *Pseudallescheria boydii* (Fung-Tomc *et al.*, 1995).

Thus, the fungal CW components and their biosynthetic pathways still are novel and important targets for the development of new antifungal drugs.

Immune Sensing and the Fungal Cell Wall

The immune system has developed very efficient strategies to control fungal pathogens, generally ensuring a result in our favor (Hernandez-Chavez *et al.*, 2017). Once the pathogen has entered the host, it is likely eliminated by phagocytic cells, such as macrophages and neutrophils of the innate immune system that belong to the first defense line (Hernandez-Chavez *et al.*, 2017; Erwig and Gow, 2016). Both kinds of phagocytic cells are efficient in fungal recognition, mainly through interaction with the CW, which contains molecules that cannot be synthesized by the host, and therefore are detected as pathogen-associated molecular patterns by various patterns recognition receptors (Díaz-Jiménez *et al.*, 2012; Becker *et al.*, 2015). It is known that polysaccharides are the most abundant CW components, and almost all of them can be recognized by specific receptors and stimulate immune responses (Erwig and Gow, 2016). However, to avoid host defense mechanisms, fungi have developed strategies to escape immune sensing (Hernandez-Chavez *et al.*, 2017).

The CW changes both composition and architecture when environmental conditions are adverse, and when the cell is under high-stress levels, contributing to the strategies required for adaptation and survival (Díaz-Jiménez *et al.*, 2012; Gow *et al.*, 2017). This is considered an advantage for some fungi since those changes can provide advantages to resist or disguise the action of immune effectors (Hernandez-Chavez *et al.*, 2017).

The recognition of CW components is essential to trigger a host protective immune response, and the outcome of this will depend on the ligands-receptors engaged and the downstream signaling pathways activated (Hernandez-Chavez *et al.*, 2017). The pattern recognition receptors are classified into four families: Toll-like receptors (TLR), NOD-like receptors (NLR), retinoic acid-inducible gene I (RIG-I), and C-type lectins (CLR), most of which are expressed in dendritic and other myeloid cells (Netea *et al.*, 2008). When interacting with *C. albicans*, TLR2 recognizes phospholipomannans, TLR4 recognizes O-linked mannan, TLR6 is involved in zymosan recognition, and TLR9 detects fungal DNA (Netea *et al.*, 2008). C-type lectin receptors are primarily membrane-bound receptors that recognize polysaccharide structures. Dectin-1 recognizes β -1,3-glucans, mannose receptor and DC-SIGN recognize *N*-linked mannans, the macrophage-inducible C-type lectin (Mincle) recognizes α -mannans, and galectin-3

Table 4 Pathogen-associated molecular patterns (PAMPs) present in some pathogenic fungi and recognition of fungal components by pattern recognition receptors (PRRs)

Pathogens	PAMPs	PRRs that recognize PAMPs
<i>C. albicans</i>	β -1,3-Glucans, β -1,6-glucans, <i>N</i> -linked mannans, <i>O</i> -linked mannans, α -mannans, α -mannose oligosaccharides, β -1,2- oligomannans, chitin.	TLR4, TLR2, TLR9, Dectin-1, Dectin-2, Dectin-3, DC-SIGN, MR, Galectin-3, Mincle
<i>A. fumigatus</i>	Galactomannan, α -1,3-glucans, β -1,3-glucans, β -1,6-glucans, β -1,4-glucans	DC-SIGN, Dectin-1, Dectin-2, TLR2, TLR4

detects mannans and β -1,2-oligomannans (Drummond *et al.*, 2011) (see Table 4). Several studies have shown that Dectin-1 mediates a wide variety of antifungal cellular responses, such as phagocytosis, cytokine, and chemokine production, which contribute to a strong inflammatory immune response. Some of these activities are stimulated when both dectin-1 and TLR2 interact with β -1,3-glucan and establish a co-stimulatory effect that positively boosts those immunological elicitors (Dennehy *et al.*, 2008; Netea *et al.*, 2008).

As mentioned, CW polysaccharides are organized in different layers, and to avoid its sensing by immune cells, fungi manage to “hide” and cover structural polysaccharides, in particular the β -1,3-glucans and chitin, with different molecules such as mannans, working as a protective shield (Heinsbroek *et al.*, 2005; Hernandez-Chavez *et al.*, 2017). This mechanism is not exclusive of *C. albicans* though. In *A. fumigatus* conidia, the hydrophobins and melanin mask the β -glucans, evading the host defense system (Steele *et al.*, 2005). The *C. neoformans* capsule masks the recognition of cell wall mannan and β -1,3-glucan; however, the cell does not go completely unnoticed by the innate immune system, because the capsule can be recognized by TLRs that trigger an inflammatory response (Marcos *et al.*, 2016). Dectin-2 and Dectin-3 receptors are also transmembrane proteins of the C-type lectin family that recognize α -mannans (Zhu *et al.*, 2013).

Chitin interacts with different receptors, in a size- and concentration-dependent manner (Da Silva *et al.*, 2009; Wagener *et al.*, 2014). At low concentrations, small particles of 1–10 μ m can induce an anti-inflammatory response through the mannose receptor, in conjunction with TLR9 and NOD2, leading to secretion IL-10 (Wagener *et al.*, 2014). Particles of intermediate size (40–70 μ m) induce a pro-inflammatory response, triggering the production of TNF α and IL-17 (Marcos *et al.*, 2016). Very large chitin particles (70–100 μ m) and very small particles < 2 μ m are inert and do not trigger an immune reaction (Marcos *et al.*, 2016). It is likely that during the infection process, and assuming that the chitin particles that remain are of intermediate size, an inflammatory process is induced and disrupts fungal cells, and from these, small particles arise to trigger an anti-inflammatory response, limiting the immunological reaction (Da Silva *et al.*, 2009).

Melanins, which are complex amorphous polymerized phenolic compounds, are also found in the CW of some dimorphic fungi. These compounds prevent complement activation, neutralize antimicrobial peptides, and protect cells from oxidative damage (Nosanchuk and Casadevall, 2006). Because of its importance in fungal virulence, the host immune system has evolved antifungal strategies that allow melanin detection (Smith and Casadevall, 2019). One of the strategies is the use of C-type lectins such as the melanin receptor MelLec, responsible for recognizing the naphthalene-diol unit of DHN-melanin. MelLec recognizes melanin from cell surface such as that found on *A. fumigatus* conidia and in other DHN-melanized fungi (Stappers *et al.*, 2018).

The Fungal Chitinases

Georgios Tzelepis and Magnus Karlsson, Swedish University of Agricultural Sciences, Uppsala, Sweden

Introduction

Chitin derives from the Greek word chiton (χιτών) meaning garment, and constitutes one of the most abundant biopolymers in nature. It consists of β -1–4 linked N-acetyl-D-glucosamine (GlcNAc) residues, forming a linear long chain and it is a structural component in many organisms. Chitin is synthesized by chitin synthases, which are plasma membrane-associated enzymes transferred by small vesicles called chitosomes (Bartnicki-Garcia, 1987). These enzymes are responsible for catalyzing the transfer of GlcNAc from uridine (UDP)-N-acetylglucosamine to the growing chitin chain. The chitin chain then inserts into the cell wall adjacent to plasma membrane, aided by hydrogen bonds (Bowman and Free, 2006).

The fungal cell wall is a dynamic compartment, contributing to hyphal ability to cope with different environmental stresses. Its composition is mostly β -1.3 and β -1.6 glucans, chitin and glycoproteins and differs from those in oomycetes and plants, where chitin is absent or exists in very small amounts (Melida *et al.*, 2013; Hinkel and Ospina-Giraldo, 2017). Chitin plays an important role in fungal cell wall rigidity and plasticity, although the percentage of chitin in filamentous fungi does not exceed 10%–20% of the total cell wall dry biomass (Specht *et al.*, 1996; de Nobel *et al.*, 2000), while in yeast-like fungi the proportion is even less (1%–2%) (Klis *et al.*, 2002). Chitin plays also a key role in fungal-plant interactions since it is recognized by plant receptors and triggers basal plant defense mechanisms resulting in pattern-triggered immunity (PTI) (Boller and Felix, 2009). Except fungal cell walls, chitin can be found in insects and nematodes (Hill *et al.*, 1991; Merzendorfer and Zimoch, 2003), in crustacean and mollusks shells (Peters, 1972; Kurita, 2006), in protozoa and algae (Mulisch, 1993; Kapaun and Reisser, 1995). However, it is absent from vertebrates and plants, meaning that it can be an appropriate target for anti-fungal drugs (Chaudhary *et al.*, 2013).

Chitinases (EC 3.2.1.52) are hydrolytic enzymes, responsible for chitin degradation. They cleave the β -1.4-bond releasing oligomeric, dimeric (chitobiose), and polymeric GlcNAc products. Yeast-like fungi contain fewer chitinase genes than the filamentous ones, and the number highly varies between species; from only one in the yeast *Schizosaccharomyces pombe* to 36 in *Trichoderma virens*. Chitinases are categorized into two glycoside hydrolase (GH) families; 18 and 19. Chitinases from filamentous fungi belong exclusively to GH18, while GH19 chitinases have been identified in the microsporidia phylum (Henrissat, 1991; Rönnebauer *et al.*, 2006). Chitinases in GH18 and GH19 families display limited sequence similarity, differences in their three-dimensional structures and in their catalytic mechanisms (Perrakis *et al.*, 1994; Brameld *et al.*, 1998). Fungal species also contain hydrolytic enzymes that degrade chitobiose to monomers. These enzymes are called N-acetylhexosaminidases (NAGases) and belong to the GH20 family (Cantarel *et al.*, 2009).

Chitinases can be classified as endochitinases or exochitinases depending on their cleavage patterns (Fig. 1). Exochitinases can cleave the chitin chain from the ends producing chitobiose, while endochitinases cleave the chitin chain at random positions (Horn *et al.*, 2006; Fig. 1). Endo- and exochitinases also show differences in their catalytic clefts; exochitinases have tunnel-shaped clefts while the substrate cleft in endochitinases are open and shallow (van Aalten *et al.*, 2001; Hurtado-Guerrero and van Aalten, 2007). Chitinase binding sites are long and contain at least five sugar units. All GH18 proteins contain a $(\alpha/\beta)_8$ barrel (TIM barrel) fold and the substrate-binding amino acids are located in loops extending from the $(\alpha/\beta)_8$ barrel (Lienemann *et al.*, 2009). Finally, GH18 have been reported to be involved in transglycosylation process as well (Boer *et al.*, 2004).

Fig. 1 The enzymatic activity of GH18s and GH20s in fungi. Endochitinases cleave the chitin chain randomly, exochitinases cleave from the open ends producing chitobiose (dimers) further cleaved by GH20 enzymes. ENGases are responsible for the deglycosylation of N-glycoproteins, cleaving the N, N-diacetylchitobiose moiety from high mannose N-linked glycans. Figure was created with BioRender.

Fig. 2 The domain structure of fungal chitinases. Abbreviations: SP: signal peptide, GH18: glycoside hydrolases family 18, CBM-1: carbohydrate binding module family 1; cellulose-binding, CBM-18: carbohydrate binding module family 18; chitin-binding, CBM-50: carbohydrate binding module family 50; LysM, GPI: glycosylphosphatidylinositol structure. Figure was created with BioRender.

Phylogenetic analyses of fungal GH18 enzymes show that they cluster in three distinct groups; A, B and C (Seidl *et al.*, 2005; Karlsson and Stenlid, 2008; Karlsson *et al.*, 2016). These groups are further subdivided in several subgroups: Group A contains four subgroups (A-II, A-III, A-IV, and A-V), group B contains six subgroups (B-I, B-II, B-III, B-IV, B-V, and B-VI) while group C is divided into two subgroups (C-I and C-II). In certain fungal species, a chitinase of bacterial origin has been identified, probably as a result from horizontal gene transfer (Ubhayasekera and Karlsson, 2012).

Chitinases in all three groups typically contain a GH18 module with the catalytic DxxDxDxE motif, necessary for chitinolytic activity (van Aalten *et al.*, 2001; Gruber *et al.*, 2011a; Tzelepis *et al.*, 2012). In addition to their catalytic module, many GH18 enzymes contain additional domains such as the carbohydrate binding module family 1 (CBM1) or CBM50 (peptidoglycan binding LysM domain) (Seidl *et al.*, 2005; Tzelepis *et al.*, 2012; Fig. 2). These modules are not involved in the catalytic activity but enhance the enzymes ability for binding to crystalline chitin (Suzuki *et al.*, 1999).

Group A Chitinases

Most chitinases in this group are predicted to have exochitinase activity since they typically have a narrow substrate catalytic cleft. Many members contain a signal peptide at their N-termini, indicating that they are targeted to the endoplasmic reticulum (ER) and are possibly secreted (Fig. 2). In addition to the GH18 catalytic module, a WD40 domain has been found in chitinases from the entomopathogenic fungus *Beauveria bassiana* (Agrawal *et al.*, 2015) (Fig. 2). This domain is involved in a variety of cellular processes, such as protein-protein or protein-DNA interactions (Xu and Min, 2011). Fungal genomes contain variable numbers of genes encoding group A chitinases. For instance, the basidiomycete *Ustilago maydis*, which causes smut disease in maize, contains only two genes (Kamper *et al.*, 2006), while the soil-borne pathogen *Fusarium oxysporum* contains 12 genes. The well-studied mycoparasitic *Trichoderma* species contain an average number of seven group A chitinase genes (Kubicek *et al.*, 2011), while the model species *Neurospora crassa* has five (Tzelepis *et al.*, 2012).

One of the best studied group A chitinases is Ech42 from *Trichoderma*. Its enzymatic function has been characterized and is atypical for group A as it is shown to possess endo-activity (Carsolio *et al.*, 1994; Hayes *et al.*, 1994). It contains at least seven subsites and cleave the chitin chain preferably between the second and the third sugar from the reducing end and it can degrade chitohexose

(GlcNAc)₆ into three (GlcNAc)₂ units (Hartl et al., 2012). When it comes to regulation and function, the *ech42* gene was highly induced under different conditions such as fungal-fungal interactions, starvation, autolysis and during cell wall degradation (Gruber and Seidl-Seiboth, 2012). Deletion of this gene did not affect *Trichoderma* mycoparasitic ability against *Rhizoctonia solani* or *Sclerotium rolfsii* (Carsolio et al., 1999), while reduced anti-fungal activity against *Botrytis cinerea* was observed (Woo et al., 1999). In *T. reesei*, three additional group A chitinase genes were expressed during similar conditions as *ech42* (Seidl et al., 2005).

In the mycoparasitic species *Clonostachys rosea*, the homolog to the *ech42* gene was also induced during interactions with *B. cinerea* and on media where chitin was the sole carbon source (Mamarabadi et al., 2008a; Tzelepis et al., 2015). Deletion of this gene led to lower *in vitro* antagonistic activity but did not reduce *C. rosea* biocontrol ability (Mamarabadi et al., 2008b). In addition to *ech42*, *C. rosea* contains seven other genes in group A (Karlsson et al., 2015; Tzelepis et al., 2015). None of these genes were induced during interactions between *C. rosea* and *B. cinerea*, *R. solani* or *F. graminearum*, while some of them were up-regulated when *C. rosea* was exposed to carbon starvation or during growth on chitin-medium, as compared to carbon rich medium (Tzelepis et al., 2015). In the entomopathogenic species *Metarhizium anisopliae*, nine group A chitinases have been identified (Junges et al., 2014). The *chimaA1* gene was up-regulated on media containing chitin or GlcNAc, while high transcript levels of *chimaA7* were measured during growth on high glucose medium (Junges et al., 2014). Furthermore, three and two genes were induced at the conidial stage or during appressoria formation, respectively (Junges et al., 2014).

In *N. crassa*, deletion of group A chitinases did not have any impact in fungal phenotypes, such as growth rate, conidiation or colony morphology, while variable transcription patterns were observed (Tzelepis et al., 2012). For instance, two genes (*gh18-3* and *gh18-4*) were induced during interaction between *N. crassa* and *F. sporotrichoides*, (Tzelepis et al., 2012). In the opportunistic human pathogen *Aspergillus fumigatus*, deletion of the group A *chiB1* chitinase gene did not cause any changes in colony morphology but resulted in lower chitinolytic activity during the autolytic phase in batch cultures (Jaques et al., 2003). However, a functional analysis of the group A *ChiB* chitinase in *A. nidulans* revealed a crucial role in autolysis (Yamazaki et al., 2007; Pocsí et al., 2009).

In the ectomycorrhizal species (ECM) *Laccaria bicolor* there are three putatively secreted group A chitinases, which are induced at different time points of ECM development, indicating a continuous degradation of chitin during the establishment of the mutualistic relationship (Veneault-Fourrey et al., 2014).

In yeast-like fungi, the number of genes encoding chitinases is lower compared to filamentous species. In the smut fungus *U. maydis*, the group A chitinase *Cts1* is involved in cytokinesis (Langner et al., 2015). Deletion of the *cts1* gene led to changes in colony morphology and sedimentation rate. *Cts1* was also shown to be essential during separation of mother and daughter cells and during filamentous growth (Langner et al., 2015), possibly by degrading chitin in the cell wall. The model yeast species *Saccharomyces cerevisiae* contains only one chitinase gene in group A (*ScCTS2*) that is involved in asci formation (Giaever et al., 2002). Deletion of the group A *AgCTS2* gene from the plant pathogenic fungus *Ashbya gossypii*, homologous to *ScCTS2*, impacted the phenotype of spores (Dünkler et al., 2008). The wild-type spores have a hyaline appearance, while spores from the *AgCTS2* mutants were speckled with dot-like, vesicular bodies. (Dünkler et al., 2008). However, deletion of the *AgCTS2* gene did not affect spore germination or polarity (Dünkler et al., 2008). Interestingly, complementation of *AgCTS2* with the homologs *ScCTS2* and *CaCTS4* from *S. cerevisiae* and *Candida albicans* respectively, restored the phenotype of spores indicating a conserved function in sporulation over species boundaries (Dünkler et al., 2008). In *C. albicans*, *CaCTS4* is induced during the yeast growth phase but down-regulated during the hyphal growth phase (McCreath et al., 1996). However, deletion of this gene did not cause any obvious phenotype (Dünkler et al., 2005). Finally, the opportunistic human pathogen *Cryptococcus neoformans* contains three homologs to the *ScCTS2* gene, which are involved in sexual reproduction of this species (Baker et al., 2009).

Certain predicted group A GH18 proteins contain mutations in the catalytic DxxDxDxE motif, indicating loss of enzymatic activity. For instance, *T. reesei* contains four genes in subgroup A-II and A-IV with these type of amino acid substitutions (Karlsson and Stenlid, 2009). The A-IV subgroup CHI18-3 protein is predicted to be localized in the mitochondria (Seidl et al., 2005) and contains two S-globulin domains, often associated with GH18 modules (Shewry and Halford, 2002). Genome analyses revealed that there are orthologs in other fungal species as well (Seidl et al., 2005; Tzelepis et al., 2012, 2015), indicating that the presence of a putative mitochondrial non-chitinolytic GH18 protein is widespread among the Sordariomycetes. It is possible that these enzymatically inactive GH18 proteins retain the ability for chitin binding, i.e., evolve into lectins, as was recently shown for the group A protein MpChi from the basidiomycete cacao pathogen *Moniliophthora perniciosa*. The enzymatically inactive MpChi binds to chitin and thereby suppresses chitin-triggered plant immunity and facilitates infection (Fiorin et al., 2018). A paralog to MpChi in the closely related cacao pathogen *M. roreri* carries a single substitution in its catalytic motif that results in reduced chitinolytic activity and was shown to suppress plant immunity in a similar fashion as MpChi (Fiorin et al., 2018). Genome mining revealed that many plant pathogens contain predicted GH18 proteins with degenerate catalytic motifs, suggesting that recognition of chitin by plant pattern recognition receptors drives evolution of chitin-scavenging lectins in plant pathogenic fungi (Fiorin et al., 2018).

Group B Chitinases

GH18 enzymes in this group are divided in six subgroups (B-I through B-VI) (Seidl et al., 2005; Karlsson et al., 2016). They are predicted to have a more shallow and wider catalytic cleft as compared to chitinases in group A, indicating endochitinase activity (Fig. 2). However, certain enzymes from the B-V subgroup have a mannosyl glycoprotein endo-N-acetyl- β -D-glucosaminidase (ENGase) type activity (Stals et al., 2010; Fig. 2). The number of group B chitinase genes varies between one in *S. cerevisiae* to 11 in mycoparasitic *Trichoderma* species (Kuranda and Robbins, 1991; Seidl et al., 2005). They are also predicted to vary in size, from small

(30–40 kDa) to large (80–90 kDa) proteins. They typically contain a signal peptide at the N-terminus, indicating that they are targeted to the ER. Cellulose-binding domains (CBM1), which also bind chitin (Boraston *et al.*, 2004), are often found in group B chitinases. *Trichoderma* species contain high numbers of chitinases with CBM1 domains (Seidl *et al.*, 2005). Experimental addition of CBM1 domains to group B chitinases in *Trichoderma* resulted in an increase of its antifungal activity (Limon *et al.*, 2001, 2004), suggesting a role in fungal-fungal interactions. Certain large group B chitinases contain a glycosylphosphatidylinositol structure (GPI anchor) in the C-terminus indicating that they are localized in the cell wall (Yamazaki *et al.*, 2008; Tzelepis *et al.*, 2012). The group B chitinase Chit33 from *Trichoderma* has been enzymatically characterized. It is a typical endochitinase having a shallow and open substrate-binding site with at least six subsites, producing (GlcNAc)₂ and (GlcNAc)₄ (Hartl *et al.*, 2012).

In *T. reesei*, the *chi18–13* gene was expressed in presence of *R. solani* cell wall components and during confrontation with *B. cinerea* (Seidl *et al.*, 2005). Similarly, its homolog in *T. atroviride* was highly induced before and during interactions with *R. solani*, indicating that group B chitinases are involved in mycoparasitic interactions (Seidl *et al.*, 2005). The group B chitinase Chi18–15/Chit36/Ech37 is an interesting example of a horizontal gene transfer event, from a bacterial donor (likely related to *Streptomyces*) to a hypocrealean acceptor, as it is found in both *Trichoderma* and *Clonostachys* (Karlsson and Stenlid, 2009; Ubhayasekera and Karlsson, 2012). Gene expression analysis showed that *chi18–15* was induced during growth on chitin and fungal cell walls, perhaps suggesting a function in nutrient acquisition (Viterbo *et al.*, 2002). Besides the *ech37* gene, the *C. rosea* genome contains two additional group B chitinases, *chiB1* and *chiB2* (Tzelepis *et al.*, 2015). The *chiB1* gene was highly induced during interactions with *R. solani*, while both genes were up-regulated on media where chitin was the sole carbon source (Tzelepis *et al.*, 2015). The saprotrophic species *N. crassa* also contains two genes in group B and one of them, *chit-1*, was induced on chitin media as well (Tzelepis *et al.*, 2012). Analysis of a *chit-1* deletion strain showed that this mutant grew slower as compared to the wild type strain, indicating a role in hyphal growth (Tzelepis *et al.*, 2012).

The fungus *M. anisopliae* contains seven genes in this group (Junges *et al.*, 2014). Among those, *chiMaB7* showed significantly higher transcript levels during infection-related conditions (blastospores, tick cuticles and appressoria), while the *chimaB4* gene was up-regulated during growth on media contained chitin or GlcNAc as sole carbon sources (Junges *et al.*, 2014). Furthermore, the *M. anisopliae* B group endochitinase CHI2 seems to be involved in virulence, since overexpression of this chitinase led to an increased efficacy of the fungus to kill the insect *Dysdercus peruvianus* while gene deletion resulted in a reduced fungal infection efficiency (Boldo *et al.*, 2009). Similarly, the CHI30 chitinase is also shown to be involved in virulence and heat shock adaptation in *M. anisopliae* (Staats *et al.*, 2013).

In the ectomycorrhizal species *Tuber melanosporum* two B group chitinases, *TmelCHT2.1* and *TmelCHT2.2*, are highly induced in the symbiotic stage. This indicates the importance of cell wall modification during the switch from the free-living to symbiotic stage (Balestrini *et al.*, 2012). Moreover, in *L. bicolor* there is a chitinase gene in this group that was up-regulated at different time points of ECM development, similar to the group A genes mentioned previously (Veneault-Fourrey *et al.*, 2014).

Regarding yeast-like species, the group B *S. cerevisiae* CTS1 chitinase gene was expressed in the mother and daughter cells during the early stages of separation (Langner and Gohre, 2016). Deletion of the CTS1 gene led to a defect in cell separation and formation of multicellular aggregates (Kuranda and Robbins, 1991). The *C. albicans* genome contains three group B chitinase homologs to CTS1, where deletion of *CaCHIT1* and *CaCHIT2* resulted in increased hyphal growth on solid media (Dünkler *et al.*, 2005). *CaCHIT2* is a typical large group B chitinase with a GPI anchor at the C-terminus (Dünkler *et al.*, 2005). Deletion of the *CaCHIT3* resulted in formation of chains of non-separated cells similar to the *S. cerevisiae* CTS1 deletion phenotype, indicating a role of these genes in cytokinesis (Dünkler *et al.*, 2005). The group B endochitinase KICTS1 from the yeast *Kluyveromyces lactis* appears to provide the same function in cytokinesis, since deletion of this gene led to inefficient cell separation (Colussi *et al.*, 2005).

As mentioned above, certain members of the B-V subgroup are shown to exhibit ENGase (EC 3.2.1.96) activity (Stals *et al.*, 2010) (Fig. 2). They contain a GH18 module with a conserved catalytic motif similar to active chitinases (DxxDxDxE) and likely evolved from an ancestral chitinolytic enzyme through neofunctionalization (Karlsson and Stenlid, 2008, 2009). Some of these enzymes are involved in deglycosylation of misfolded N-glycoproteins in the ER-Associated Degradation (ERAD) process, cleaving the glycoside bond in the N,N-diacetylchitobiose moiety as shown in Fig. 1 (Suzuki *et al.*, 2002). Filamentous ascomycetes typically contain a cytosolic ENGase, while a second, putatively secreted protein has been identified in certain species (Tzelepis *et al.*, 2017). In general, GH18 ENGases are absent from yeast-like species, such as *Saccharomyces*, *Candida*, and *Cryptococcus* (Tzelepis *et al.*, 2017). In Basidiomycetes, the situation is mixed with ENGases being absent from *Heterobasidium*, *Ustilago*, and *Puccinia* genera, while *Schizophyllum* and *Stereum* species have one putative ENGase in their genomes (Tzelepis *et al.*, 2017). Deletion of cytosolic ENGases led to severe phenotypic changes in filamentous ascomycetes (Dubey *et al.*, 2012; Tzelepis *et al.*, 2012). In *N. crassa*, deletion of the cytosolic *gh18–10* ENGase resulted in slower mycelial growth, increased conidiation and tolerance to abiotic cell wall stress agents, and reduced amount of secreted proteins (Tzelepis *et al.*, 2012). Similar results were observed in *T. atroviride* Δ Eng18B strains, which is homolog to the *gh18–10* gene (Dubey *et al.*, 2012). Interestingly, this mutant lost its antagonistic ability against *B. cinerea* as well, possibly as an effect from the reduced secretion phenotype (Dubey *et al.*, 2012). Further analysis on Eng18B enzymatic function revealed that it is an active de-glycosylating enzyme, involved in the ERAD process (Tzelepis *et al.*, 2014a).

Group C Chitinases

Chitinases in this group are predicted to exhibit exochitinase activity although no member from this group has yet been biochemically characterized. They are present only in filamentous ascomycetes and are subdivided to two subgroups (C-I and C-II)

(Karlsson and Stenlid, 2008; Gruber *et al.*, 2011a). They show sequence similarities to the α/β subunits of the killer toxin zymocin produced from the dairy yeast *K. lactis* and are therefore often referred to as “killer toxin-like” chitinases (Magliani *et al.*, 1997). In *K. lactis*, the function of the α subunit chitinase is to degrade the antagonist cell wall in order to facilitate penetration of the γ subunit, which is the active toxin (Butler *et al.*, 1991). A similar function has been hypothesized for the group C chitinases (Tzelepis and Karlsson, 2019). Genome analysis in *Trichoderma* species revealed that aggressive mycoparasitic species, such as *T. virens* and *T. atroviride*, contain higher number of C group chitinase genes, as compared to the weak mycoparasite *T. reesei* (Ihrmark *et al.*, 2010).

Most C group chitinases are predicted to have an intact catalytic domain, while few of them contain mutations that would render them devoid of chitinolytic activity (Karlsson and Stenlid, 2009; Gruber *et al.*, 2011b). As it was shown in Fig. 2, group C chitinases contain a signal peptide at the N-terminal and multiple domains (Tzelepis and Karlsson, 2019). In the C-I subgroup, chitinases usually contain one to three carbohydrate-binding family 18 (CBM18) together with the catalytic GH18 module, both located at the N-terminus (Fig. 2). Members in the C-II subgroup typically contain one CBM18 and two LysM CBM50 domains (Gruber *et al.*, 2011a,b; Tzelepis *et al.*, 2012, 2014b). The CBM18 domains bind to chitin and it is suggested to increase adherence of chitinases to the substrate (Boraston *et al.*, 2004). The CBM50 modules have peptidoglycan and chitin binding affinity (Buist *et al.*, 2008) and their role in fungal-plant interactions is well established, since they bind to chitin and stealth fungal hyphae from plant recognition (de Jonge *et al.*, 2010). This mechanism seems to be universal in the fungal kingdom, since it has been described in both ascomycete and basidiomycete phytopathogenic species (Mentlak *et al.*, 2012; Takahara *et al.*, 2016; Dörfors *et al.*, 2019). Furthermore, some members in the C-II subgroup contain transmembrane domains at the C-terminus, indicating a plasma membrane localization (Tzelepis *et al.*, 2012; 2014b; Fig. 2). Finally, it has been reported that a small protein domain (Hce2) is fused to the C-termini of certain C-II chitinases (Stergiopoulos *et al.*, 2012). This protein domain is homologous to the necrosis-inducing Ecp2 effector, which has previously been found in phytopathogenic species such as *Mycosphaerella graminicola* and *M. fijiensis* (Stergiopoulos *et al.*, 2010). A chitinase from *T. reesei* is predicted to contain an epidermal growth factor-1-like module at the C-terminus, potentially involved in protein-protein interactions (Wouters *et al.*, 2005). Although the exact roles of Hce2 and EFG-1 remain to be elucidated, it is speculated that they serve a role similar to the zymocin γ -subunit (Tzelepis and Karlsson, 2019).

When it comes to regulation of C-group chitinases, it was initially speculated that the primary function of these enzymes was in fungal-fungal interactions. However, gene expression data later suggested their involvement in other aspects of fungal biology as well. In the *N. crassa* genome, there are three members in the C group. The C-I member *chi18-9* was induced during carbon starvation conditions and not during interactions with fungal species, in contrast to the other C-II members, *chi18-6* and *chi18-8*, which were induced during interspecific interactions and during self-interactions (Tzelepis *et al.*, 2012). However, expression patterns differed during interactions with different fungal species, ascomycetes (*B. cinerea*) versus basidiomycetes (*R. solani*), suggesting that differences in cell wall composition may control regulation (Tzelepis *et al.*, 2012). The *A. nidulans* genome contains four genes in C-II subgroup and gene expression analysis showed that all of them were highly induced during interactions either with ascomycetes (*B. cinerea*) or basidiomycetes (*R. solani*), while there were not induced during interactions with *Phytophthora* species, which lacks chitin in the cell wall, or when dead cell wall material was the only carbon source (Tzelepis *et al.*, 2014b). Expression studies of C-group chitinases have been described in other fungal species as well, such as in the thermophile *Myceliophthora thermophila* where up-regulation was observed during growth on straw (Kolbusz *et al.*, 2014), and in the mycoparasite *Tolyocladium ophioglossoides* during parasitism of truffle tissue (Quandt *et al.*, 2016).

Analysis of expression patterns in *Trichoderma* species support the concept that C-group chitinases are involved in different aspects of fungal life and not only in interspecific interactions (Seidl *et al.*, 2005; Gruber *et al.*, 2011a,b). For instance, in *T. atroviride*, all eight C-group chitinase genes in *T. atroviride* were up-regulated during interactions with *B. cinerea* but not with *R. solani*, and no induction was observed on dead *R. solani* cell wall material (Gruber *et al.*, 2011a). Furthermore, four genes were induced on media where chitin was the sole carbon source, indicating their involvement in nutrient acquisition, while two of them were induced in the central part of the fungal colony, with older hyphae, compared to younger hyphae in periphery, suggesting an additional role in hyphal branching and autolysis (Gruber *et al.*, 2011b). In contrast, gene expression analyses in *T. virens* showed that only four of totally 14 C-group chitinase genes were induced during interactions with either *B. cinerea* or *R. solani*, while 11 of them were induced on fungal cell wall material (Gruber *et al.*, 2011b).

The structure of chitin also seems to influence the induction of these genes, since different genes were up-regulated by different forms of chitin (crude or colloidal) (Gruber *et al.*, 2011b). Finally, *Trichoderma* genome analyses revealed that *tal* genes, predicted to contain only CBM50 modules without any catalytic domain, are often clustered and regulated together with C-group chitinase genes (Gruber *et al.*, 2011a). Functional analysis showed that they are involved in hyphal growth (Seidl-Seiboth *et al.*, 2014). Furthermore, Tal6 protects hyphae from chitinases, increases *Trichoderma* virulence and modulates the activation of plant immunity (Romero-Contreras *et al.*, 2019). In contrast, the mycoparasite *C. rosea* contains a reduced number of genes encoding C-group chitinases as compared to *Trichoderma* mycoparasitic species. There is one member in the C-I and one in the C-II subgroup (Tzelepis *et al.*, 2015). Transcriptional analysis in this species showed that none of these genes were induced in interaction with *Fusarium* species, while the C-I member was only induced on chitin media (Tzelepis *et al.*, 2015). *Metarhizium anisopliae* contains four genes in this group that appeared to be constitutively expressed (Junges *et al.*, 2014).

Functional analyses of C-group chitinases have been conducted in model filamentous species, such as *N. crassa* and *A. nidulans*. In *N. crassa*, deletion of either C-II subgroup genes did not affect its growth or tolerance to abiotic stress conditions (Tzelepis *et al.*, 2012). In *A. nidulans*, deletion of either of the four C-II subgroup genes resulted in increased biomass production in liquid cultures. Deletion of *chiC2-2*, predicted to contain the Hce2 domain, resulted in mutants with reduced *in vitro* antagonistic ability against *B. cinerea* (Tzelepis *et al.*, 2014b). Moreover, three deletion strains showed to be slightly more tolerant in abiotic stress conditions (Tzelepis *et al.*, 2014b).

Fig. 3 Proposed functions of fungal chitinases. (A) chitinases in filamentous species have a function in fungal-fungal interactions, degradation of exogenous chitin for nutrient acquisition, autolysis and hyphal branching. Inactive fungal chitinases are involved in perturbation of chitin-triggered immunity during fungal-plant interactions. (B) chitinases in yeast-like fungal species are involved in cytokinesis, such as separation of mother and daughter cells during budding and separation and formation of spores. Figure was created with BioRender.

In *Trichoderma* mycoparasitic species, functional studies are limited. It is possible that gene redundancy in these species prevents observable phenotypes. The only study comes from deletion of a C group gene in *T. atroviride*, where deletion led to reduced conidiation (Seidl-Seiboth *et al.*, 2014). However, this gene carries mutations in the catalytic motif indicating that its chitinolytic activity has been abolished (Gruber *et al.*, 2011a). In contrast, deletion of the *C. rosea* C-II chitinase *chiC2* gene resulted in mutants with reduced *in vitro* antagonistic activity against *B. cinerea* and *R. solani*, but not against *Fusarium graminearum* (Tzelepis *et al.*, 2015). However, deletion of *chiC2* did not affect the biocontrol ability of *C. rosea* against *B. cinerea* (Tzelepis *et al.*, 2015).

Concluding Remarks

Chitinolytic enzymes are present in all fungal species and they are involved in degradation of chitin, an important structural component of fungal cell walls. Fungal chitinases from filamentous fungi belong to GH18, while a single GH19 chitinase has been described in the microsporidial species *Encephalitozoon cuniculi* (Rönnbäumer *et al.*, 2006), a very basal fungal group. Based on their catalytic activities, they can be categorized as exochitinases, which cleave the chitin chain from the ends, or as endochitinases, which cleave the chitin at random positions. Exochitinases release chitobiose, which is further degraded by GH20 NAGases. Phylogenetically, fungal GH18 genes are divided into three groups A, B, and C, further sub-divided in many subgroups. Since gene redundancy is one of the main problems in chitinase functional studies, their precise roles in fungal biology still remain unclear. From the available studies, data show that chitinases play roles in different aspects of fungal physiology, such as degradation of exogenous chitin for nutrient release, in mycoparasitic interactions, during carbon starvation and autolysis, in cell wall remodeling and hyphal growth (Fig. 3(A)). In yeast-like species, the number of chitinase genes is lower, typically between one and four, and hence more functional data are available. In these species, chitinases are involved in cytokinesis, such as mother and daughter cell separation during budding (Fig. 3(B)), and in sporulation, such as spore formation and separation (Fig. 3(B)). The killer toxin-like chitinases in group C is an interesting case. They are present only in filamentous ascomycetes and contain multiple domains such as CBM50 and CBM18, and all of them are predicted to be secreted (Fig. 2). In some of them, the Hce2 domain, homologous to the Ecp2 effector, is present. Many aspects of these chitinases remain to be elucidated. Since transcriptional data show that

induction of these genes is often triggered in fungal-fungal interactions, important questions concerns host specificity and cell wall composition or elicitors produced by the living cells that may trigger their expression. Furthermore, the role of the CBM50 and Hce2 modules should be clarified. It is speculated that they may be released as individual peptides after secretion through proteolytic activity, and may function in self-protection and as a toxin, respectively.

GTPases in Hyphal Growth

Hyphal Growth in Filamentous Fungi

Filamentous fungi are an evolutionarily flourishing group of microorganisms of significant ecological importance (Evans and Hedger, 2001). They have a considerable impact on our economy and ecosystem because important enzymes derive from fungi with applications in food, textile, recycling and other industries (Cairns *et al.*, 2018). In addition, many fungi are human and plant pathogens that pose a threat to public health and agriculture (Fisher *et al.*, 2012). Among the filamentous fungi there are also the mycorrhizal fungi, which bring countless benefits to the host plant (Smith and David, 2008), and edible fungi, such as truffle, one of the most valuable foods (Hall *et al.*, 2003). Last but not least, fungi are extremely important for understanding many functions of eukaryotic cells in vastly researches and their secondary metabolism is of significant pharmaceutical relevance (Keller *et al.*, 2005).

A better understanding of cytoplasmic organization and behavior can lead to higher and more diverse levels of insight to biology of cells and their evolutionary histories.

The dominant cell type of filamentous fungi are hyphae, which are filamentous of elongated cells that expand at the apex of the tip cell (Steele and Trinci, 1975). The processes involved in the growth of hyphae have affected many scientists for many years. Thanks to the progress in efficient technological DNA sequencing and gene deletion methods, today there is a drastic increase in the number of data. Despite these new resources, filamentous growth is a critical aspect of fungal biology that is not yet comprehensively understood (Meyer *et al.*, 2016). Hyphae exhibit a highly polarized form of cell growth that requires the regulation of numerous processes including cell wall synthesis, polarized vesicle transport, exocytosis, endocytosis, cytoskeletal function, turgor pressure, organelle positioning and bulk cytoplasmic flow. These actions result in apically growing tube-shaped hyphae.

Cell Wall Synthesis

Hyphal growth is accompanied by the secretion of exoenzymes that participate in lysis of the substrate or are involved in the synthesis of the fungal cell wall (Archer and Wood, 1995). The fungal cell wall plays a significant role in development and integrity of the fundamental architecture required for survival and proliferation of the filamentous fungus. The structure of the cell wall is composed typically of polysaccharides and glycoproteins, that can be considered as an extracellular gel-like matrix (Ruiz-Herrera and Ortiz-Castellanos, 2019). The cell wall of most filamentous fungi contains β (1,3)- β (1,4)- β (1,6)- β (1,7)- glucans, α (1,3)-glucans, chitin, galactomannoproteins, and other less well-characterized glucans. It has been seen that in the alkaline-insoluble fraction are present fibrils of β (1,3)- and β (1,7)-glucans and chitin. Glycoproteins together with alkaline-soluble polysaccharides form an amorphous matrix (Klis *et al.*, 2006). These matrix glycoproteins are presynthesized and packaged into vesicles at the Golgi and delivered along cytoskeleton to the specific points of wall growth. After exocytosis glycosylphosphatidylinositol (GPI) anchors glycoproteins to the plasma membrane (Steinberg *et al.*, 2017).

The polysaccharides are synthesized by enzymes chitin synthases (CHS) and glucan synthases (GS), which are transported on the cell membrane in an inactive form within vesicles, where the enzymes are inserted to synthesize in situ the chitin and β (1,3)-glucans (Sanchez-Leon *et al.*, 2011). Chitin is thought to be the major polysaccharide found in the *Neurospora crassa* septae (Potapova, 2014). Filamentous fungi generally contain several genes encoding CHSs and they are organized into seven different groups or classes, as opposed to three classes of CHSs in yeast or dimorphic species, which correlates with the lowest chitin content in their cell wall (Riquelme and Bartnicki-Garcia, 2008). The 1–3-glucan synthase complex (GSC) synthesizes β (1,3)-glucans: it contains a catalytic subunit (Fks) and a regulatory subunit (Rho1). Only one essential *Fks* gene has been identified in filamentous fungi. While in *Saccharomyces cerevisiae* there are two *Fsk* genes and they haven't distinct functions. Catalysis products operated by Fsk transmembrane protein poured out of the plasma membrane. Rho1 is a GTPase which is synthesized in the endoplasmic reticulum and inserted into plasma membrane by geranylgeranylation (Inoue *et al.*, 1999).

Today the most accepted view proposes that cell wall-loosening enzymes, such as chitinases and glucanases, participate in the breakage of polysaccharide chains, such as chitin and β (1,3)-glucans, allowing the addition of newly arrived material and generating free ends, substrate for cross-linking enzymes, that rigidify the cell wall (Riquelme *et al.*, 2018).

The Spitzenkörper and Vesicles Pathway

The apex of filamentous fungi is a highly dynamic region where cell growth and morphogenesis occur through the coordinated events of exocytosis, cytoskeletal dynamics and cell wall synthesis. Spitzenkörper (Spk) is where secretory vesicles self-assemble. Using phase-contrast light microscopy, the Spk is observed as a phase-dark body, in most taxa, is partially or completely surrounded a phase-bright central core (Roberson *et al.*, 2010). The Spk is important for hyphal growth and its position in the growing hypha determines the directionality of growth (Riquelme *et al.*, 2000). At the ultrastructural levels the Spk contains vesicles of different sizes,

actin, microtubules and above all ribosomes, suggesting that translation of mRNA and protein synthesis happen in the hyphal apex (Howard and Aist, 1979). It is thought that the Spk functions as a vesicles supply center. It receives Golgi derived vesicles that releases exocytic vesicles in a controlled manner: in fact, the Golgi cisternae are distributed along the hyphae (Riquelme *et al.*, 2018). It determines an exocytosis gradient that fixes the shape of the fungal apex (Bartnicki-García *et al.*, 1989). In *N. crassa* the enzymes responsible for the synthesis of the cell wall, CHS and GCS, were located in the Spk. Specifically, CHS was identified at the core of Spk, where microvesicles concentrate and GCS at the Spk outer layer (Riquelme *et al.*, 2007). A biochemical stratification of Spk was detected in *Aspergillus nidulans*, but not the precise location of CHS synthetases (Takeshita *et al.*, 2015).

The biogenesis and release of vesicles take place through different passages, as in other eukaryotes: scission from the donor membrane-vesicle formation, vesicle transport, vesicle docking and vesicle fusion. There are involved coat complexes, which promote vesicle formation and recognize cargo-sorting signals; tethers which interact with coat proteins and mediate docking; and SNAREs (soluble NSF [N-ethylmaleimide-sensitive factor] attachment protein [SNAP] receptors) which facilitate the fusion between the donor and target membrane (Bonifacino and Glick, 2004). Rab GTPases are molecular switches to regulate these steps of vesicular transport along cytoskeletal elements. In *N. crassa* homologous genes have been identified that encode for Rab GTPases that occupy two distinct parts of Spk (Gould and Lippincott-Schwartz, 2009): YPT-1Rab1 was found in the core, while SEC-4Rab8 and YPT-31Rab11 were located in the outer layer. This suggests that distinct Rabs regulate the traffic of the different vesicle populations to the Spitzenkörper (Sánchez-León *et al.*, 2015). FRAP (fluorescence recovery after photobleaching) experiments allowed the identification of the time of the vesicular turnover at the Spk, which is rates from 20 to 40s (Sánchez-León *et al.*, 2015). Scientists speculate that the vesicles of Rab that reach the Spk derive from the apparatus of Golgi (Pantazopoulou *et al.*, 2014).

Once the vesicles have reached the membrane, they are fused through exocysts. In *A. nidulans*, *Candida albicans* and other filamentous fungi, fluorescently imprinted exocysts components localized at growth sites, but if there is a tethering mechanism of exocytosis it is little understood (Riquelme *et al.*, 2014). After exocytosis, the last stage of secretory pathway, vesicles fuse with their target membrane by SNAREs interactions. The synaptobrevin vesicular SNARE protein SynA was observed at the Spk of *A. nidulans* and at the apical plasma membrane (Taheri-Talesh *et al.*, 2008).

It seems that exocytosis and endocytosis work in tandem for hyphal morphogenesis (Delgado-Alvarez *et al.*, 2010; Upadhyay and Shaw, 2008). Endocytosis is the result of the extra plasma membrane released by exocytosis (Riquelme *et al.*, 2018).

Structure and Action Mechanism of Small GTPases

Structure

The small GTPases proteins have been studied by crystallographic analysis, and it has emerged that they consist of five fairly conserved domains responsible for binding with GTP, from G1 to G5. G1 motif (I) is a purine nucleotide binding signal; G2 motif (E) is in one of two segments that redirects with GDP or GTP binding function and provides major component of the effector binding surface; G3 motif (II) is involved in Mg^{2+} binding; G4 (III) motif brings the hydrogen bond into contact with the guanine ring; the G5 (IV) motif creates indirect associations with the guanine nucleotide (Wennerberg *et al.*, 2005; Colicelli, 2004; Goitre *et al.*, 2014).

Action Mechanism

Small GTPases perform their physiological activity switching the molecular structure in two forms which support mutual transformation, GTP-binding activated state and GDP-binding non-activated state, which can also be called as "ON" state and "OFF" state, respectively (Jhonson and Chen, 2012).

The multiple biological functions of the small GTPases proteins are mediated through a highly regulated GTP/GDP binding cycle. Three different classes of proteins are required for the regulation: (1) guanine nucleotide exchange factors (GEFs), which stimulate the GTP-GDP exchange reaction; (2) GTPase-activating proteins (GAPs), which stimulate the GTP-hydrolyzing reaction; and (3) guanine nucleotide dissociation inhibitors (GDIs), which antagonize the actions of GEFs and GAPs and regulate the subcellular localization and the cycling of GTPases between membrane and cytosol (Hoffman *et al.*, 2000; Rivero *et al.*, 2002). The active GTP-bound GTPases interact with a myriad of effectors that relay upstream signals, inducing a number of downstream events, including rearrangements of the actin cytoskeleton network and protein kinase-dependent induction of transcription (Hall, 1998; Jaffe and Hall, 2005).

GEFs and GAPs coexist in most cells, increasing the diversity of signals that regulate small GTPases activity (Goitre *et al.*, 2014). Guanine nucleotide dissociation inhibitors (GDIs) are contrary to exchange factors (Menotta *et al.*, 2008). GDI specifically binds GDP-bound GTPase and inhibits GDP release (Rak *et al.*, 2003; Malagnac *et al.*, 2013).

Classification

Ras proteins were the first to be discovered, as their mutation led to various forms of cancer. Subsequently, the researches brought to light several GTPase enzymes with a 3D structure similar to Ras. To date, over 150 members of this family are known, therefore it is counted among the superfamilies.

Ras-like proteins have been named small G proteins. They are divided into five subfamilies, according to their amino acid sequence, their structure and function (Kahn *et al.*, 1992).

In the various organisms these proteins belonging to each subfamily have been extensively studied, and it has been found that they can have overlapping functions. Ras are involved in cell proliferation, Rho in cell morphology, Ran plays a role in nuclear transport and Rab and Arf in vesicular traffic (Goitre *et al.*, 2014).

Ras

Ras superfamily is the largest and most diverse superfamily. In mammals it mainly plays a role in regulating the mechanisms of immunity and inflammation (Colicelli, 2004; Goitre *et al.*, 2014). The GTPases of this group are a general component of the eukaryotic signaling pathway and contribute to the processes of development, proliferation, differentiation and survival of the eukaryotic cell.

It has also been shown that the different isoforms (the highly conserved H-, K- and N-Ras) perform specific biological functions (Haigis *et al.*, 2008; Karnoub and Weinberg, 2008).

Rho

Small GTPases of the Rho family function as molecular switches in separate or correlative signaling pathways that tightly regulate diverse cellular functions (Karnoub *et al.*, 2004). These signaling pathways link the cytoplasmic receptors to activate cytoskeleton reorganization and the subsequent biological effect. They are ubiquitously expressed in eukaryotes and are grouped in three major subfamilies: Rho, Rac, and Cdc42.

The Rho GTPases were thought to be primarily involved in the regulation of cytoskeleton organization (Hall, 1998) required for vesicle trafficking, motility, adhesion and morphogenesis (Kaibuchi *et al.*, 1999; Rivero and Somesh, 2002). Moreover, they play the same significant role in modulating cell polarity, genetic transcription, cell cycle progression, extracellular matrix (ECM) remodeling apoptosis, tumorigenesis (Johnson, 1999; Jaffe and Hall, 2005) and various enzymatic activities (using NADPH oxidase activity to generate the reactive oxygen, ROS) (Li *et al.*, 2014).

Rab

Rab subfamily is the largest subfamily in small GTPase Protein family (Pereira-Leal and Seabra, 2001). In *Arabidopsis* 93 small GTPases family members were detected, and among them 57 belong to Rab subfamily. Rab GTPases modulate membrane traffic processes (vesicle formation, vesicle movement along actin and tubulin networks, membrane fusion). Through these processes the surface proteins are transported from the Golgi apparatus to the plasma membrane and are then recycled.

Over 60 types of Rab GTPases have been found, with the function of stimulating and regulating the docking and fusion of the trafficking vesicles to the membranes; at least one is found for each cytoplasmic organelle and the different membranes have different Rab proteins.

Arf

The Arf protein (ADP ribosylation factor) is the main regulator of the biosynthesis of trafficking vesicle in eukaryotic cells (Donaldson and Jackson, 2011; Ma *et al.*, 2020). It has strong homology with Rab GTPase, but unlike this, which acts in a single step in the transport process to the membrane, Arf acts in several steps. For example, Arf1 protein functions in retrograde transport from Golgi to the ER through recruitment of COPI coated vesicle proteins and in the Trans-Golgi-Network (TNG, ie the formation of vesicles) (Beck *et al.*, 2009); Arf1 also regulates recruitment of clathrin through AP-1, AP-3 and AP-4 complexes (Wennerberg *et al.*, 2005).

Ran

Small GTPase Ran is one of the most expressed in eukaryotes (Moore, 1998). It is involved in nucleocytoplasmic transport, participating both to the import and the export from the nucleus of proteins and RNAs, modulate the formation of cell spindle apparatus, cell cycle progression, structure and function of nucleoplasm, cell redox reaction, RNA synthesis and processing, etc. (Sazer and Dasso, 2000). Nuclear import receptors such as importin beta bind their substrates only in the absence of GTP-bound RAN, forming the tripolymer, and release them upon direct interaction with GTP-bound RAN, while export receptors behave in the opposite way. Thereby, Ran controls cargo loading and release by transport receptors in the proper compartment and ensures the directionality of the transport. Similarly Ran regulates the export of the core (Kim *et al.*, 2001).

Function of Small GTPase in Hyphal Growth

GTPases are molecular switches or timers in many cellular processes (Gilman, 1987). They are involved in signal transduction in response to activation of cell surface receptors, including transmembrane receptors; protein biosynthesis at the ribosome; regulation of cell differentiation, proliferation, division and movement; translocation of proteins through membranes; transport of vesicles within the cell, and vesicle-mediated secretion and uptake, through GTPase control of vesicle coat assembly (Threadgill *et al.*, 1997; Parri and Chiarugi, 2010).

In general, we can summarize from numerous scientific researches, that the different GTPases have the following prevalent roles: Ras sub- family modulation of the gene expression; Rho subfamily regulation of cytoskeleton reorganization, cell wall synthesis,

cell cytokinesis, and MAP kinase cascade pathway; Rab sub-family and Sar/Arf subfamily modulate the trafficking and formation of coated vesicles; Ran subfamily acts in transport into and out of the cell nucleus during interphase and also in mitosis.

Numerous studies have concerned their involvement in hyphal growth in filamentous fungi, in the acquisition of the fundamental polarity for growth directionality and in the underlying cytoskeletal morphological changes.

Ras

Ras GTPases are fundamental for detecting and responding to environmental signals in all eukaryotes (Goitre *et al.*, 2014; Arkowitz and Bassilana, 2015). Their action is expressed through the activation of numerous effectors belonging to kinases pathways (such as the conserved Ras/cAMP/protein kinase A, PKA) (D'Souza and Heitman, 2001; Fimia and Sassone-Corsi, 2001; Gerits *et al.*, 2008). Many studies, using mutant deletion, have shown that Ras plays a key role in hyphal growth and morphogenesis.

S. cerevisiae has two Ras (Ras1 and Ras2), one Rap (Rsr1/Bud1) and one Rheb (Rhb1) ortholog, whereas *Schizosaccharomyces pombe* has only one Ras, one Rheb, but no apparent Rap ortholog.

In particular Ras 2 in *S. cerevisiae* is involved in hyphal growth consequent to starvation (Mösch *et al.*, 1996). Its connection to nutrient availability in fission yeast has been shown also by Chen *et al.* (2019) in 2019. Since the conserved NDR/LATS kinase Orb6 responds to nutritional cues, Orb6 increases the protein levels of a Ras1 GTPase activator, the guanine nucleotide exchange factor Efc25 and regulates Ras1 GTPase activity. These evidences remark the involvement of Ras in promoting cell adaptation, balancing the opposing demands of promoting cell growth and extending chronological lifespan.

In Daniels (2012) it was shown that the formation of the peculiar finger structure, induced in *C. albicans* by the presence of CO₂, is coordinated by Ras 1, and also in *Cryptococcus neoformans* Ras 1 is involved in hypoxia-induced growth (Chang *et al.*, 2014).

In filamentous fungi the role of Ras is crucial for hyphal growth, as reported in literature (Arkowitz and Bassilana, 2015; Kanauchi *et al.*, 1997; Feng *et al.*, 1999; Leberer *et al.*, 2001; Zhu *et al.*, 2009; Huang *et al.*, 2009; Som and Kolaparthi, 1994; Fortwendel *et al.*, 2004; Truesdell *et al.*, 1999; Alspaugh *et al.*, 2000; Waugh *et al.*, 2002; Lee and Kronstad, 2002; Boyce *et al.*, 2005; Bluhm *et al.*, 2007; Zhang *et al.*, 2012a,b; Knabe *et al.*, 2013; Minz Dub *et al.*, 2013).

In filamentous fungi the activation mechanism of Ras, dependent on the GTP/GDP bound cycle, has been studied by means of mutants and the corresponding GEFs (Guanine nucleotide Exchange Factors) and GAPs (GTPase Activating Proteins) have been shed light on.

Numerous studies on the Cdc25 homolog in *Ustilago maydis*, *Yarrowia lipolytica*, *C. albicans*, *A. nidulans* and *Colletotrichum orbiculare* have highlighted its importance in the onset of pathogenesis (in *U. maydis*, Müller *et al.*, 2003), in filamentous growth (*C. albicans*, Shapiro *et al.*, 2009), in the maintenance of polarity (in *A. nidulans* Harispe *et al.*, 2008), in hyphal morphology (*C. orbiculare*, Schubert *et al.*, 2006; Harata and KuboRas, 2014). Therefore Ras, like all GTPases, depends on the GTP/GDP cycling.

GTPase Ras is localized at the level of plasma membrane through the farnesylation of a cysteine in the conserved CAAX tail, in combination with a palmitoylation (Eisenberg *et al.*, 2013; Wright and Philips, 2006). In yeasts and *Candida*, the palmitoylation occurs on a single cysteine residue that allows the membrane anchoring. In filamentous fungi, two conserved palmitoylation cysteines have been identified (Fortwendel *et al.*, 2012; Nichols *et al.*, 2009). Ras localization is spread evenly across the membrane in *C. albicans* and in *Aspergillus fumigatus* (Fortwendel *et al.*, 2012; Piispanen *et al.*, 2011).

The palmitoylation is crucial for several cellular events, e.g. mating in *S. pombe* (Onken *et al.*, 2006), hyphal growth at extreme temperature in *C. neoformans* (Nichols *et al.*, 2009), while in *A. fumigatus* is necessary for hyphal growth, cell wall development, and virulence (Fortwendel *et al.*, 2012). Ras, depending on its location, has specific effectors in the different membrane compartments.

A Ras GTPase associated protein, MadC a GTPase activating protein (GAP), affects the circadian clock output in *N. crassa*, as reported in Polaino *et al.*, 2017, thus it is a target for photoreponses.

Moreover in pathogen filamentous fungi such as *Magnaporthe oryzae* Ras is involved in appressorium formation and in fungal infection. In fact, as shown in Hendy *et al.* 2019, the action of farnesyltransferase β -subunit gene, RAM1, that regulate post-translational farnesylation process can affect the proper localization of many proteins in signal transduction, including Ras, and consequently can modulate hyphal growth and sporulation.

In Martin-Vicente *et al.* 2019, another Ras regulator, a Ras-subfamily-specific guanine nucleotide exchange factors (RasGEFs) in the human pathogen *A. fumigatus*, has shown to affect the properly timed polarity establishment during early growth and branch emergence as well as for cell wall stability, in that it is essential for the integration of multiple signaling networks performed by Ras.

Rho subfamily

Rho

Cdc42 and Rho1 were shown to be required for viability and for cell polarization in *S. cerevisiae* and *S. pombe* (Bi and Park, 2012; Perez and Rincón, 2010; Arkowitz and Bassilana, 2015; Brauns *et al.*, 2020). Moreover Rho1 is involved in cell wall synthesis, in that it modulates glucan synthesis and the specific MAP-kinase pathway.

Among filamentous fungi, Rho 1 is essential for viability and hyphal growth in *C. albicans* and *U. maydis* (Arkowitz and Bassilana, 2019; Wakade *et al.*, 2020; Lu *et al.*, 2014; Corvest *et al.*, 2013; Pham *et al.*, 2012; Smith *et al.*, 2002; Dünkler and Wendland, 2007), while not in *Y. lipolytica* and *Fusarium oxysporum* where it is nonessential (León *et al.*, 2003; Martínez-Rocha *et al.*, 2008). Cell wall

integrity (Arkowitz and Bassilana, 2019; Corvest *et al.*, 2013; Edlind *et al.*, 2005) and virulence (Roemer *et al.*, 2003) of *C. albicans* depends on Rho1; it is the regulatory component of a complex (β -1,3-glucan synthase complex, GSC) responsible of β -1,3-Glucans synthesis (Arkowitz and Bassilana, 2019).

In *U. maydis* the expression alteration of Rho1 determinates growth defects. In Paul *et al.*, 2014 an interaction between Rho1 and an ammonium transporter crucial for hyphal growth regulation has been reported. Studies on *C. neoformans* revealed the presence of three Rho1 homologs, Rho1, Rho10 and Rho11 (Lam *et al.*, 2013), with different roles, such as viability, temperature reactivity and cell wall integrity. Dominant active forms of Rho1 are somewhat defective in capsule formation, suggesting this GTPase may also be important for virulence. Mutations in Rho1 GEF, rom2, exhibited alterations in temperature sensitive growth, actin organization, cell morphology and infectious capacity (Fuchs *et al.*, 2007; Tang *et al.*, 2005).

Conditional rho1 mutants provoke swell at the hyphal tip, apical lyses at the non-permissive temperature, hypersensitivity to cell wall damage and limitation in cell wall integrity MAP kinase signaling in *N. crassa*, (Richthammer *et al.*, 2012). The mutation of GAP and GEF Rho regulators causes similar morphological effects, in addition, a defect in sub-apical branching and sensitivity is observed in GAP mutants if exposed to an actin depolymerization substance (Richthammer *et al.*, 2012; Vogt and Seiler, 2008).

In *A. nidulans* the hydrolysis blockage and the alteration of the GAP domain induces a serious defect in germ tube emergence. In *A. fumigatus*, Rho1 is crucial (Dichtl *et al.*, 2012) and its GEF regulator (Rom2) is fundamental in cell wall integrity (Samantaray *et al.*, 2013). In *Ashbya gossypii*, there are two Rho1 homologs, Rho1a (RhoH) and Rho1b (Rho1): the presence of only one required for viability, but they are both critical for cell wall integrity and remodeling in dimorphic and filamentous fungi (Köhli *et al.*, 2008; Walther and Wendland, 2005; Wendland and Philippsen, 2001). Similar effects are shown in the Tus1 GEF mutant (Lengeler *et al.*, 2013).

In *C. albicans*, *U. maydis*, *A. fumigatus* and *N. crassa*, Rho1 and/or its GEF Rom2 are localized to the hyphal apex (Caballero-Lima *et al.*, 2013; Dichtl *et al.*, 2010; Pham *et al.*, 2012; Richthammer *et al.*, 2012; Samantaray *et al.*, 2013). In *N. crassa* the presence of Rho1 GAP Lrg1 to the hyphal tip is dependent on the growth rate (Vogt and Seiler, 2008).

In *C. albicans* active Rho1 was broadly associated with the hyphal tip, consistent with the Rom2 distribution, and a ~10-fold increase in the levels of active Rho1 was observed at the septum upon cell division (Corvest *et al.*, 2013). In *A. gossypii*, Rho1b was localized predominantly to the hyphal tip, whereas Rho1a was localized to the septum at 25°C (Köhli *et al.*, 2008), while after heat shock conditions both Rho GTPases were localized to the entire hyphal cortex, demonstrating their different roles.

Cdc42

Cdc42 is the main regulator of cell polarity and has been studied in numerous filamentous fungi.

Cdc42 and Rac have similar roles, as shown in *A. nidulans* (ModA and RacA), *N. crassa* (CDC-42 and RAC-1), and *U. maydis* (Cdc42 and Rac1) (Virag *et al.*, 2007; Araujo-Palomares *et al.*, 2011; Lichius *et al.*, 2014; Harris and Momany, 2004; Riquelme *et al.*, 2018) in particular as concern cell polarity machinery. Both anchor the membrane via a typical C-terminal CAAX motif. In *N. crassa*, the spatial distribution of these Rho GTPases changes during development. Cdc42 and Rac regulate the chemotropism exhibited during germ tube development and together with Cdc24, Cdc42, are localized at the apical dome in mature hyphae.

In *Penicillium marneffei* and *C. albicans* Cdc42 is necessary for viability, (Bassilana *et al.*, 2003; Boyce *et al.*, 2003; Boyce *et al.*, 2001; Mahlert *et al.*, 2006; Michel *et al.*, 2002; Ushinsky *et al.*, 2002), as well as cell polarization. The GEF Don1 is critical for cell separation and localizes to endosomal vesicles (Hlubek *et al.*, 2008; Schink and Bölker, 2009; Weinzierl *et al.*, 2002).

In *U. maydis*, Cdc42 is required for virulence and cell separation during budding, yet this protein does not appear to be essential for cell polarity (Mahlert *et al.*, 2006).

Cdc42 has a role in polarized growth in *C. albicans* and strains with reduced levels of Cdc42 arrested growth (Bassilana *et al.*, 2003; Arkowitz and Bassilana, 2015; Ushinsky *et al.*, 2002). Furthermore, Cdc42 and its activator Cdc24 are required for the yeast to hyphal transition, tropic responses and virulence (Bassilana *et al.*, 2003; Brand *et al.*, 2008; VandenBerg *et al.*, 2004), and the level of active Cdc42 is critical for the initiation and maintenance of hyphal growth (Bassilana *et al.*, 2005), as shown in Corvest *et al.* 2013. Also the localization of its GAP is important for maintaining active Cdc42 at apical level (Zheng *et al.*, 2007a,b).

In *A. nidulans* functional analysis of the homologs of the yeast GEF Cdc24 and the yeast GAP Rga1 shown that Cdc24 is important for the establishment of hyphal polarity and localizes to hyphal tips, and that Rga1 is necessary for the suppression of branching in developing conidiophores.

Results showed in Menotta *et al.*, 2007 suggest a fundamental role of Cdc42 in cell polarity development in *Tuber borchii* Vittad. Immunolocalization experiments revealed an accumulation of Cdc42 in the apical tips of the growing hyphae, and very interestingly, the expression of the constitutively active TbCdc42 Q63L transformed in yeast cells switched on a series of evident morphological modifications, since elongated shape, and giant cells and cell aggregations were present.

Moreover, in a few fungi, this highly conserved small GTPase also plays roles in cell separation and/or cytokinesis, which may reflect its importance in septin-dependent processes. In fact, in yeast the ring diameter is set through the dynamic interplay of septin recruitment and Cdc42 polarization, establishing it as a model for size homeostasis of self-assembling organelles (Kukhtevich *et al.*, 2020).

Also in *C. neoformans* Cdc42 is necessary for septin localization (Ballou *et al.*, 2010).

In *A. gossypii*, Cdc42 is essential for spore germination (Wendland and Philippsen, 2001).

In contrast, Cdc42 is not required for viability in other filamentous fungi, e.g. *N. crassa*, *A. nidulans*, *A. niger*, *Magnaporthe grisea* and *Claviceps purpurea*. In conditional cdc42 mutants *N. crassa* hyphae grew in an uncoordinated, zig-zag fashion (Seiler and Plamann, 2003), were distorted (loss of polarity) and periodic reinitiation of growth at the swollen tips were visible

(Araujo-Palomares *et al.*, 2011). Moreover *cdc24* mutants exhibited increased tip branching and *bem1* mutants resulted in chains of spherical cells (Seiler and Plamann, 2003), even if subsequent studies concluded that *bem1* is not critical for hyphal polarity establishment in *N. crassa* (Schürg *et al.*, 2012).

Cdc42 was found to be important also for hyphal branching in *A. nidulans*, *Curvularia trifolii* and *Schizophyllum commune* (Chen *et al.*, 2006; Virag *et al.*, 2007; Weber *et al.*, 2005; Si *et al.*, 2016). In *A. niger* a reduced and delayed germ tube formation was observed in the *cdc42Δ* mutant, while no significant effects were observed in hyphal morphology (Kwon *et al.*, 2011). It has been reported a role in virulence mechanisms in *M. grisea*, where *cdc42* is probably involved in appressorium formation (Zheng *et al.*, 2009; Dagdas *et al.*, 2012). In the plant pathogen *C. purpurea*, Cdc42 was found to be important for pathogenicity, branching and conidiation (Scheffer *et al.*, 2005).

In some filamentous fungi Cdc42 is important for mycorrhiza development, as shown in Menotta *et al.*, 2007, where RT-real-time PCR analyses revealed an increased expression of *Tbcdc42* during the phase preparative to the instauration of symbiosis, in particular after stimulation with root exudate extracts.

From research carried out on filamentous fungi, it is shown that in most cases *cdc42* has a fundamental role in hyphal growth and hyphal branching.

As concern Cdc42 localization, in *C. albicans* this GTPase is located at apical tip level (Bassilana and Arkowitz, 2006; Crampin *et al.*, 2005; Hazan and Liu, 2002) in F-actin dependent way (Hazan and Liu, 2002), as well as its coordinators Cdc24 and Bem1 (Bassilana *et al.*, 2005; Pulver *et al.*, 2013). The GAP Bem3 localized to a diffuse patch at the hyphal tip, which sometimes appeared as a ring, whereas the GAP Rga2 was largely cytoplasmic (Court and Sudbery, 2007; Zheng *et al.*, 2007a,b). Also in *A. gossypii*, *N. crassa*, *C. purpurea* and *S. commune* Cdc42 is visualized a cortical cap or crescent at the hyphal tip (Araujo-Palomares *et al.*, 2011, Herrmann *et al.*, 2014; Köhli *et al.*, 2008; Weber *et al.*, 2005). Cdc24 and Bem1 are located at the hyphal tip in *A. gossypii* and in *Epichloë festucae*; while in *N. crassa* Cdc24 and Bem1 localized similarly to the hyphal tip (Köhli *et al.*, 2008; Takemoto *et al.*, 2011) and they appear more broadly distributed (Araujo-Palomares *et al.*, 2011; Schürg *et al.*, 2012). While Cdc42 was observed at the hyphal septa, active Cdc42 was not detected at this location (Corvest *et al.*, 2013; Hazan and Liu, 2002).

Rac

The Rac small GTPase is highly homologous to Cdc42, has similar functions but also specific roles. In *P. marneffei* and *C. albicans*, Rac1 is not essential for viability but is important for filamentous growth (Bassilana and Arkowitz, 2006; Boyce *et al.*, 2003; Hurtado *et al.*, 2000). In *P. marneffei*, a *rac1* deletion strain produced aerial hyphae, extensive apical branching and altered actin cytoskeleton (Boyce *et al.*, 2003). In *C. albicans*, it seems that the lacking of active *rac1* does not cause an alteration in the actin cytoskeleton, but can compromise the invasive growth (Bassilana and Arkowitz, 2006). Mahlert *et al.* (2006) reported that Rac1 is not essential in *U. maydis*, but has a role in cell morphology and hyphal growth.

Two Rac paralogs (Rac1 and Rac2) were found in *C. neoformans* (Ballou *et al.*, 2013). Defective Rac1 impaired completely the hyphal growth (Vallim *et al.*, 2005), but Rac1 nor Rac2 were necessary for virulence in an inhalation model of cryptococcosis (Ballou *et al.*, 2013; Vallim *et al.*, 2005). Rac has a less important role in hyphal branching while it is fundamental in polarized growth during response to specific inducers.

Rac mutants generated hyperbranching at apical tip in *N. crassa*. Rac and Cdc42 together were found to be necessary for polarity establishment and maintenance (Araujo-Palomares *et al.*, 2011).

Rac alone is not essential for viability in the three *Aspergillus* species, *A. fumigatus*, *A. nidulans* and *A. niger*, (Kwon *et al.*, 2011; Virag *et al.*, 2007; Si *et al.*, 2016), but double *rac*, *cdc42* mutants were inviable in *A. nidulans* and *A. niger* (Kwon *et al.*, 2011; Virag *et al.*, 2007). In *A. fumigatus* and *Aspergillus niger* *rac* deletion mutants exhibited multiple axes of polarity, with increased apical branching (Kwon *et al.*, 2011).

In *M. grisea*, *rac1* defect was compatible with life, while conidial and appressorium development was repressed (Chen *et al.*, 2008). In *C. purpurea*, hyphae of both *rac* and *cla4* mutants were shorter and wider than wild-type cells and exhibited hyperbranching (Rolke and Tudzynski, 2008).

The p21-activated kinase Cla4 is an important effector of Rac in fungi (Cotteret and Chernoff, 2002; Boyce and Andrianopoulos, 2011; Bustelo *et al.*, 2007). BcRac, the Rac homolog of the gray mold fungus *Botrytis cinerea*, was found to have Cla4 as effector; BcCla4 protein was found to mediate all the Rac driven processes, including hyphal growth and morphogenesis, conidia production and pathogenicity (Minz-Dub and Sharon, 2017).

In *Trichoderma reesei* Rac1 defect induces hyperbranching, apolar growth and impacts on cellulase activity (Fitz *et al.*, 2019).

Therefore, in filamentous fungi, Rac is central for filament branching.

As regards the localization in *P. marneffei* Rac1 it is found at the level of the hyphal apices and in the division sites, while in *C. albicans* it is widespread in the cell cytoplasm. Instead Rac1 was observed in the nucleus in *C. albicans* (Bassilana and Arkowitz, 2006; Boyce *et al.*, 2003; Vauchelles *et al.*, 2010). The two forms of *rac* present in *C. neoformans*, on the other hand, are localized at the membrane level, both cellular and organellar (Ballou *et al.*, 2013). The two forms of Rac in *N. crassa* are located in a differentiated way under the apical region, reflecting the different functions attributed to them (Araujo-Palomares *et al.*, 2011).

Rab

Rab GTPases are the largest group of the small GTPases family, plays a pivotal role in the secretion of proteins and serve as regulators of the intracellular membrane trafficking system (Mizuno-Yamasaki *et al.*, 2012; Li and Marlin, 2015; Pfeffer, 2017).

Fungal hyphae extend by apical growth and this process requires continuous polarized trafficking of secretory vesicles to a special structure called Spitzenkörper (SPK).

Rab family orchestrates the vesicle secretion in all eukaryotic cells, in coordination with protein coats, molecular motors, tethering factors and SNAREs (Grosshans *et al.*, 2006). Rab proteins are as signaling molecules, safeguarding the arrival of vesicles to the specific domains (Jin *et al.*, 2011; Hervé and Bourmeyster, 2018).

In addition, in *N. crassa* YPT-1 has been shown to be involved in the CHS traffic activity through tests of immunoprecipitation followed by mass spectrometry that supposed YPT-1 is one of the CHS-1, CHS-4 and CHS-5 interacting proteins (Fajardo-Somera *et al.*, 2015) and through characterization by density gradient centrifugation (Verdín *et al.*, 2015). Benli *et al.* (1996) indicated Ypt31 and Ypt32 (Rab11 orthologs) in *S. cerevisiae* as helpers of vesicular carriers.

RabE, orthologue of Rab11, in *A. nidulans* has been seen to play a role in the transformation of the Golgi's cisternae into post-Golgi (Pantazopoulou *et al.*, 2014). Sánchez-León *et al.* (2015) have found the different localization of the homologs of *S. cerevisiae* YPT-1 (Rab1) and YPT-31 (Rab11) in *N. crassa*: laser scanning confocal microscopy showed that YPT-1 occupied the Spk microvesicular core and YPT-31 was at the macrovesicular layer of the Spk. This research confirmed that distinct Rabs participate in micro and macro vesicles pathway.

Other studies suggested that YPT-31 is not significant for hyphal growth, because through FRAP analysis, the YPT-31 levels in some fungal systems are similar in *N. crassa* where the growth was lower (Jones and Sudbery, 2010; Pantazopoulou *et al.*, 2014).

With quantitative superresolution localization microscopy of live *A. nidulans* cells it has discovered that chitin synthase ChsB, located in Spk, is transported with two different speeds for hyphal growth (Zhou *et al.*, 2018). These findings provide the characteristic intermittent cell growth and shed light on how downstream regulators coordinate the vesicles release. In *S. cerevisiae*, Sec4p is the Rab8 homolog that is involved in the last anterograde vesicles transport (Walworth *et al.*, 1992).

Sec4p, as YPT-31, GS-1 and FKS-1, in *N. crassa* is allocated at the marginal layer of the Spk (Sánchez-León *et al.*, 2015). Sec4p associates with Sec15p and this interaction can control the exocyst assembling (Guo *et al.*, 1999). But the location seen by Sánchez-León *et al.* in 2015, suggests that Sec4p can also takes part in the transport of GSC (Sánchez-León and Riquelme, 2015).

Nevertheless, further investigation is necessary to explain the role of Sec4p for GSC and especially how the different Rabs come into play in the pre-exocytary phase.

Arf

In all eukaryotes, membrane/protein trafficking to the plasma membrane is mediated by vesicular transport between different cellular compartments (Donaldson and Jackson, 2011). The small GTPases of the Arf (ADP-ribosylation factor) family guide membrane/protein trafficking. In *S. cerevisiae* has been describing the processes controlled by the ADP ribosylation factors of the Arf/Sar family, in particular vesicle formation and trafficking, cytoskeletal rearrangements, cell polarity and budding (Roth, 1999; Lambert *et al.*, 2007; Suda *et al.*, 2018). *S. cerevisiae* Arf family includes seven members: Arf1, Arf2, Arf3, Arl1, Arl3, Cin4, and Sar1. Ar1 and Arf2 together with Arl1 have regulating role in the secretory pathway. Specifically Arf1/2 are involved in the formation of COPI vesicles and clathrin coated vesicles at cis and trans Golgi cisternae, respectively (Roth, 1999; Suda *et al.*, 2018).

In contrast to *S. cerevisiae*, there are still unknown aspects of Arf/Arl proteins in filamentous fungi. Labbaoui *et al.* (2017) investigated Arf/Arl proteins in *C. albicans* and they identified Arf2 and Arl1 as key regulators of membrane traffic, critical for this fungal hyphal growth and virulence. However ArfB in *A. nidulans* is the *S. cerevisiae* Arf3 homolog, and it is involved in polarized growth and endocytosis (Lee *et al.*, 2008), also as its homolog in *M. oryzae*, Arf6, during asexual development (Labbaoui *et al.*, 2017). Also within the Nematode-trapping (NT) fungus *Arthrobotrys oligospora* was found an ortholog of Arf-GAP of *S. cerevisiae*, Aoglo3, to be involved within the regulation of multiple cellular processes such as mycelial growth, conidiation, environmental adaption, endocytosis and pathogenicity. Moreover, the deletion of Aoglo3 gene, in particular, shown growth defects, a rise in hyphal septation and the Aoglo3 mutant sporulation capacity decreased (Ma *et al.*, 2020).

Fiedler *et al.* (2018) characterized ArfA in *A. niger* and demonstrated that it impacts fungal growth rates, hyphal tip morphology and protein secretion. Subcellular localization experiments of fluorescently labeled proteins associated with cytoskeletal elements provided evidence that the position of the endocytic actin ring is impacted by both lowered and elevated levels of ArfA expression, and ArfA secretion at septa level was hypothesized. Fluorescent microscopy shown that the position of the actin ring at the hyphal tip is affected by the ArfA expression in *A. niger*.

Moreover it was reported in yeast, that Arf3 regulates the Bud1 GTPase activating protein Bud2p and the GTP/GDP exchange factor Bud5; since Bud1 affects Cdc24, and subsequently Cdc42, Arf3 is upstream an important hierarchical GTPase cascade that regulate actin dynamics necessary for polar growth (Hsu and Lee, 2013).

The actin ring is the site of endocytosis, and the location of this cytoskeletal apparatus at the hyphal tip is vital for polar growth (Taheri-Talesh *et al.*, 2008). In *A. nidulans*, the actin ring is maintained precisely 1–2 µm behind the hyphal apex, even in rapidly growing hyphae (Taheri-Talesh *et al.*, 2008). It is seen that the *A. niger* glucoamylase might not only be secreted at the hyphal tip, but also at hyphal septa as previously suspected (Gordon *et al.*, 2000). This is consistent with studies using *A. oryzae*, where the major extracellular protein alpha-amylase was observed to localize in the space between the plasma membrane and cell wall at septa [i.e., the septal periplasm (Hayakawa *et al.*, 2011)]. Septal exocytosis is required for secondary cell wall thickening, intercalary hyphal growth, and branch initiation in filamentous fungi (Hayakawa *et al.*, 2011; Read, 2011). Therefore, ArfA is also required for normal exocytic and/or endocytic processes at the hyphal septum.

Membrane Transporters, an Overview of the Arbuscular Mycorrhizal Fungal Transportome

Nuria Ferrol, Department of Soil Microbiology and Symbiotic Systems, Zaidín Experimental Station, Spanish National Research Council (EEZ-CSIC), Granada, Spain

Introduction

Membrane transport in fungi contributes to key aspects of their growth and development, and to their adaptation to multiple ever-changing environments. These transport systems, consisting of one or more proteins embedded in the cell membranes, enable the cell to ensure the uptake of essential nutrients and the efflux of toxic compounds, and play key roles in ion homeostasis and cell signaling. Transport proteins can be simple channels or pores created in the membrane, that facilitate diffusion of compounds down their concentration gradient, or active transporters that require metabolic energy to drive the transport of solutes against their concentration gradient (Busch and Saier, 2004).

One of the main changing extracellular conditions is nutrient availability. Adaptations to these conditions require nutrient-sensing mechanisms in order to supply specific nutrients and to adapt cellular metabolism, growth and development accordingly. One fundamental mechanism for this adaptation is regulated transport across cell membranes through the coordinated uptake or efflux of nutrients across the plasma membrane and intracellular membranes. Recently, the identification of transceptors, membrane proteins that act both as transporters and receptors, establishes a link between transport and signaling (Steyfkens *et al.*, 2018).

Membrane transport has been a main topic of research during the last century and remains an active field of study. Among fungi, most research has been performed in *Saccharomyces cerevisiae*. Even before the emergence of high-throughput genome sequencing techniques, genes encoding transport proteins of this model yeast were cloned and characterized. Progression into the genomics era led to rapid advances in the catalog of available fungal genomes for mining and *in silico* predictions of all membrane transporters of a fungal species (De Hertogh *et al.*, 2002; Grigoriev *et al.*, 2014). It is now known that approximately 10% of a yeast genome corresponds to membrane transporters (De Hertogh *et al.*, 2006) and it is firmly established that many of these transport proteins belong to protein families conserved in organisms ranging from bacteria to humans (André, 1995). The important transport processes operating in several fungal species have been described (Benito *et al.*, 2011; Hora'k, 2013; Dutta and Fliegel, 2018) and excellent comprehensive reviews have summarized the yeast transport processes (Conrad *et al.*, 2014; Ramos *et al.*, 2016). For a detailed description of the membrane transport proteins readers are referred to the Transporter Classification Database (TCDB) webpage (See Relevant Websites Section). This chapter summarizes the general types of transport processes that enable translocation of substrates across fungal membranes and provides an overview of the transport systems characterized so far in arbuscular mycorrhizal (AM) fungi, the most ancient and widespread fungal plant symbionts (Smith and Read, 2008). AM fungi are obligate biotrophs that enhance host plant nutrient acquisition in exchange for carbon compounds. This requires an efficient nutrient transport system in which the transporters are key actors.

Types of Transport Processes

Transport of solutes across biological membranes may occur via simple diffusion, facilitated diffusion or active transport (Fig. 1).

Simple Diffusion

Simple diffusion is a passive mechanism that does not involve the input of energy by the fungus to accomplish the movement of gases or uncharged small molecules, such as ethanol, across the membrane lipids. Simple diffusion can be affected the plasma membrane composition and proton motive force, but specific transporters are not usually involved.

Facilitated Diffusion

In facilitated diffusion solutes are transported across the membrane along a concentration with the assistance from membrane proteins, such as channels or transporters (also named facilitators, carriers, or permeases). No metabolic energy is expended since this transport process is governed by the concentrations of the molecule of interest on either side of the membrane. If the concentration on one side of the membrane barrier is higher than on the other side, the movement of molecules through the connecting channel or facilitator will naturally occur, in order to balance the concentrations on both sides of the membrane (Eddy and Barnett, 2007).

Channels

Membrane channels are complexes of membrane proteins or peptides that mediate passive transport of solutes by forming an aqueous diffusion pore. They can operate by different mechanisms, being the most common the gated channel, which requires a

Fig. 1 Types of membrane transport processes. Passive transport processes do not require energy input. Lipid soluble solutes enter the cells via simple diffusion. In facilitated diffusion solutes are transported along a concentration gradient through channels or carriers. Solute moving against a concentration gradient are transported at the expense of metabolic energy. Primary transporters couple ATP hydrolysis to the transport of a solute against its concentration. The plasma membrane H^+ -ATPase generates the proton motive force required for the activity of the secondary transporters. Symporters transport two solutes in the same direction and antiporters in the opposite direction. X (anion or a solute moved against its concentration), C (cation).

trigger, such as a change in membrane potential in voltage-gated channels, to unlock or lock the pore opening. Ion channels play a key role in cation homeostasis, being the best characterized the *S. cerevisiae* efflux voltage-gated K^+ channel Tok1, which is activated by membrane depolarization (Ketchum *et al.*, 1995).

Aquaporins, belonging to the family of major intrinsic proteins, also form pores in the membrane facilitating mainly the transport of water into and out of the cell. Aquaporins form tetramers in the cell membrane, with each of the four monomers acting as a water channel. The driving force for water movement is the gradient of chemical potential of water (osmotic and/or hydrostatic pressure) between both sides of the membrane and predicted to occur in either direction (Finkelstein, 1984). In the fungal kingdom, there are five groups of fungal aquaporins, with two groups of classical aquaporins and three groups of aquaglyceroporins. Although water is the main substrate transported by aquaporin, they can transport other substrates, such as glycerol, H_2O_2 , NH_4^+ , boron, urea, and CO_2 (Sabir *et al.*, 2016).

Another important family of channels is the ammonium channel transporter (AMT) family. AMT proteins are homotrimers, in which each subunit contains a narrow pore through which substrate transport occurs. As expected for a channel, NH_3 uniport appears to occur by energy-independent, non-concentrative, bidirectional diffusion (Loque *et al.*, 2007), but NH_4^+ may be the true substrate requiring in this case metabolic energy (Fong *et al.*, 2007). AMT proteins appear to function as channel/carrier hybrids. *S. cerevisiae* has three AMT homologs named Mep1, Mep2, and Mep 3, that also transport methylammonium and present different affinities for ammonium. Mep2 has been shown to function both as a transporter and as a sensor, generating a signal that regulates filamentous growth in response to ammonium starvation (Lorenz and Heitman, 1998).

Copper (Cu^+) transporters of the Ctr family also function by a channel mechanism that mediate Cu^+ uptake by a passive, membrane potential-dependent mechanism (Dumay *et al.*, 2006). They function as trimers forming a channel in the membrane. Three homologs have been described in *S. cerevisiae*, two located in the plasma membrane (Ctr1 and Ctr3) and one in the vacuolar membrane (Ctr2) (Puig and Thiele, 2002). However, multiple homologs have been identified in *Schizosaccharomyces pombe* (Beaudoin *et al.*, 2013).

Transporters or carriers

In contrast to a channel, a transporter is assumed to transfer the solute across the membrane by undergoing reversible conformational changes that expose its solute-binding site alternately on each side of the membrane. For example, in *S. cerevisiae* hexoses are taken up by facilitated diffusion through hexose transporters. The high rates of phosphorylation of hexoses together with its subsequent metabolism provide the driving force for continued translocation into the cell. The *S. cerevisiae* hexose transporter family is comprised of 17 members, with different substrate affinities for glucose (Leandro *et al.*, 2009). Given that facilitated diffusion systems operate optimally around their substrate affinity value or K_m , it is believed that the wide range of substrate affinities of the *S. cerevisiae* hexose transporters (ranging from 1 to 100 mM) will enable uptake of glucose and other hexoses across the wide range of hexose concentrations present in the yeast environment. However, in other organisms uptake of hexoses requires metabolic energy, as it is presented below for the AM fungal hexose RIMST2 (Helber *et al.*, 2011).

Active Transport

Active transport is the process of moving solutes across a membrane against a concentration gradient and requires metabolic energy. There are two types of active transporters, primary transporters that use adenosine triphosphate (ATP), as a source of energy and secondary transporters that use an electrochemical gradient.

Primary active transporters

Primary transporters are integral membrane proteins that couple ATP hydrolysis to the transport of a solute against its concentration. These transporters play a key role in the generation of gradients of protons and cations across the membranes and in the detoxification of toxic compounds. There are four types of primary transporters: P-type ATPases, V-ATPases, F-ATPases, and ABC transporters.

P-type ATPases

P-type ATPases are transmembrane proteins that couple ATP hydrolysis to the efflux of a cation out of the cytosol. They function as pumps for various cations (H^+ , Ca^{2+} , Cu^{+2+} , Zn^{2+}) across the plasma or intracellular membranes. The plasma membrane H^+ -ATPase is by far the most extensively studied ATP-driven transport system in yeast (Serrano *et al.*, 1986) and in many other fungi (Ghislain and Goffeau, 1991; Kühlbrandt *et al.*, 2002). Its primary function is to provide an energy source for the transport of nutrients into the cell. The yeast PMA1 H^+ -ATPase is an electrogenic enzyme since it extrudes positive charges forming a membrane potential (negative on the inside) that serves as a source of energy for the activity of secondary active transporters (Barnett, 2008).

A sub-family of P-type ATPases comprises the Ca^{2+} -transporting ATPases, which in *S. cerevisiae* play a key role in calcium storage in the vacuoles and in the secretory compartments of the endoplasmic reticulum and Golgi through the activity of the Pmc1 and Pmr1 Ca^{2+} -ATPases, respectively (Cunningham and Fink, 1994). A second sub-family of P-type ATPases is the $\text{P}_{1\text{B}}$ -type ATPases also known as Heavy Metal ATPases that pump metals across membranes against their electrochemical gradient. The best-characterized member of this sub-family is the product of the CCC2 gene that is required for exporting Cu^{2+} from the cytosol to the secretory pathway (Yuan *et al.*, 1995).

V-ATPases

V-ATPases consist of peripheral and integral membrane subunits. They are proton pumps that acidify organelles, such as vacuole, lysosomes, endosomes, and Golgi (Kane, 2006; Forgac, 2007). Together with the plasma membrane H^+ -ATPase plays a key role in fungal pH and in the generation of the proton gradients that serve as a source of energy for secondary transporters.

F-type ATPases

F-type ATPases are located in the mitochondria and function mainly as an ATP synthase utilizing ADP, inorganic phosphate and an electrochemical gradient of protons.

ABC (ATP binding cassette) transporters

Members of the ATP-binding cassette (ABC) superfamily catalyze the ATP-dependent transport of chemically diverse compounds across the plasma membrane or intracellular membranes. They play key roles in the efflux of xenobiotic compounds, physiological substrates, and toxic intracellular metabolites. The yeast genome contains 30 ABC proteins that are classified in different sub-families (Paumi *et al.*, 2009). The best-characterized yeast ABC transporter is the vacuolar yeast cadmium factor that transports glutathione-complexes to the vacuole and plays a role in detoxifying metals (Li *et al.*, 1996).

Secondary transporters

Antiporters

An antiporter is a membrane protein that transports two molecules at the same time in the opposite direction. Usually the transport of one ion or molecule is against its electrochemical gradient and the movement is powered by the free energy stored in the proton gradient generated by the plasma membrane H^+ -ATPase or the vacuolar ATPase. A primary example of this type of transporters is the family of Na^+/H^+ antiporters or Na^+/H^+ exchangers (NHEs), proteins essential to keep the Na concentrations low in the cytosol (Dutta and Fliegel, 2018). For example, the genome of *S. cerevisiae* encodes three Na^+/H^+ antiporters: the plasma membrane Nha1 that has similar affinity for Na^+ and K^+ (Bañuelos *et al.*, 1998), Nhx1 that is the main proton-coupled antiporter mediating potassium or sodium transport across the vacuolar membrane (Cagnac *et al.*, 2007) and ScKha1p that is localized in the Golgi (Maresova and Sychrova, 2005).

Two other examples of antiporters are the family of calcium proton exchangers that play a key role in calcium homeostasis (Cunningham and Fink, 1996) and the cation diffusion facilitator (CDF) family that function by H^+ antiport for metal efflux (Montanini *et al.*, 2007). Members of the CDF family transport heavy metals including cobalt, cadmium, iron, zinc and possibly nickel, copper and mercuric ions and are involved in metal tolerance/resistance by efflux (Paulsen and Saier, 1997).

Symporters

Symporters are proteins that simultaneously transport two molecules across a membrane in the same direction. The most widely held model for this process has the molecules binding to the transport protein that is exposed on the external surface of the

membrane. In an energy-dependent process, these molecules are driven through a central region of the protein to emerge on the opposite side of the membrane. The protein molecule remains stationary. Examples of symporters are the family of sulfate transporters that mediate transport of SO_4^{2-} by using the electrochemical gradient of protons (Cherest *et al.*, 1997) and the Pho family of phosphate transporters that also use the proton gradient as a driven force for translocation of phosphate ions in a symport manner (Bun-ya *et al.*, 1991). The potassium transporters of the Trk family normally function also as H^+/K^+ or Na^+/K^+ symporters and are thought to be driven by the membrane potential created by the plasma membrane H^+ -ATPase. Fungi usually have two Trk systems (Corratgé-Faillie *et al.*, 2010). In *S. cerevisiae*, Trk1 and Trk2 strongly differ in their affinity for potassium, being Trk1 and high-affinity K transporter and Trk2 a low-affinity one (Ko and Gaber, 1991).

Amino acid transport is also a primary example of a symport transport process since amino acids are generally present in the natural environment at concentrations far lower than those found in the cytoplasm. Amino acids are, therefore, taken up against its concentration gradient by members of the amino acid transporter (AAT) family (Gournas *et al.*, 2018). Members of the proton-dependent oligopeptide transporter (POT/PRT) family also function by a proton symport process (Hauser *et al.*, 2001).

The mechanism of transport of several secondary transporters has not been determined yet. This is the case of the members of the Zinc (Zn^{2+})-Iron (Fe^{2+}) permease (ZIP) family (Gaither and Eide, 2001). The energy source for metal translocation is not ATP and several driving forces, including bicarbonate, pH dependence or phosphorylation, have been proposed.

Why Arbuscular Mycorrhizal Fungi?

Arbuscular Mycorrhizal (AM) fungi, belonging to the subphylum Glomeromycotina within the Mucoromycota (Spatafora *et al.*, 2016), are complex but extremely successful soil-borne microorganisms. They are obligate biotrophs that establish a compatible interaction with plants, called arbuscular mycorrhiza, by either avoiding or suppressing plant defense reactions while redirecting host metabolic flow to their benefit without being detrimental to their host (Gianinazzi-Pearson, 1996). AM fungi have accompanied land plants through evolution and survived across periods of important environmental change to become ecologically and agriculturally important symbionts that improve overall fitness of most land plants (Smith and Read, 2008). Substantial evidence supports their use as natural biofertilizers and bioprotectors in agriculture (Gianinazzi *et al.*, 2010; Berruti *et al.*, 2016).

The main benefit for the plant is an improved mineral nutrition, especially of phosphorus, nitrogen, zinc and copper. The fungus develops in the soil an extensive network of extraradical hyphae that overgrows the soil surrounding the plant roots and functions as an additional absorptive surface area for the plant increasing its capacity to forage nutrients beyond their depletion zone (Fig. 2(A) and (B)). In return, the plant provides to the fungus the carbon compounds, either in the form of carbohydrates or lipids, required to complete its life cycle. This nutrient exchange between partners occurs in the arbuscules, specialized and highly branched structures formed by the fungus in the root cortical cells (Fig. 2(C)). AM fungal nutrient uptake from the soil and coordinated exchanges between the plant and the fungus at the symbiotic interface formed in the cortical cells colonized by arbuscules is controlled by the coordinated regulation of specialized plant and fungal membrane transport systems. Despite nutrient exchange between partners and nutrients themselves seem to be at the heart of the evolutionary success of this symbiosis, the mechanisms underlying these processes are not yet fully understood. So far, molecular players controlling nutrient transport processes in the symbiosis have been mainly identified and characterized on the plant side (Wipf *et al.*, 2019). However, much less is known on the fungal side.

AM fungi are obligate biotrophs incalcitrant to pure culture in the absence of a host plant, possess coenocytic hyphae and multinucleated spores and so far no sexual reproduction has been described yet (Gianinazzi-Pearson *et al.*, 2012). These characteristics introduce inherent limitations in the application of standard techniques, such as genetic transformation and mutant generation/characterization, for their study, which greatly hinders advances in the knowledge about gene function in these crucial group of fungi. Nevertheless, significant progress has been made recently in our understanding of their biology through the release and subsequent mining of genome sequences. *Rhizophagus irregularis* (formerly named *Glomus intraradices*)

Fig. 2 (A) *In vitro* culture of *R. irregularis* in association with carrot roots. (B) Extraradical mycelium of *R. irregularis* showing hyphae and spores. (C) Arbuscule of *R. irregularis* detected by wheat germ agglutinin-FITC labeling on a root section.

DAOM197198 was the species chosen for the first genome-sequencing project on AM fungi (Tisserant *et al.*, 2012). Nowadays, the genomes or transcriptomes of several AM fungi, such as *Rhizophagus clarum* (Kobayashi *et al.*, 2018), *Diversispora epigaea* (formerly *Glomus versiforme*; Sun *et al.*, 2019), *Gigaspora margarita* (Salvioli *et al.*, 2016), and *Gigaspora rosea* (Tang *et al.*, 2016) have been sequenced and annotated. These gene repertoires have enabled the identification of genes potentially encoding for transport proteins in different AM fungal species.

AM Fungal Transportome

Current knowledge on the transportome in AM fungi, that is, the complete repertoire of fungal genes encoding membrane transporters is still low. Much of the information generated on the Glomeromycotina transportome focuses on the model species *R. irregularis*.

Primary Active Transporters

P-type ATPases

As mentioned above, P-ATPases are enzymes that couple ATP hydrolysis to the transport of a cation out of the cytosol, being the plasma membrane H^+ -ATPase an essential protein for the functioning of the secondary transporters. In the Glomeromycotina, two H^+ -ATPases genes have been characterized in the AM fungus *Funneliformis mosseae* (formerly, *Glomus mosseae*) (Ferrol *et al.*, 2000; Requena *et al.*, 2003). Both genes are differentially expressed in the different developmental stages of the fungus and are more highly expressed in the intraradical than in the extraradical mycelium. Expression of *GmHA5* is up-regulated by phosphate, the main nutrient transferred by the fungus to the plant, suggesting that this isoenzyme provides the proton motive force required for phosphate uptake by a symport transport process. Interestingly, *GmHA5* was found to be highly expressed in the arbuscules (Balestrini *et al.*, 2007). As found for *F. mosseae*, *R. irregularis* also expresses two plasma membrane H^+ -ATPase genes (Tisserant *et al.*, 2012). A total of 35 genes putatively encoding P-type ATPases were identified in the *R. irregularis* transcriptome, ten potentially encoding Ca-ATPases likely involved in Ca homeostasis and four encoding heavy metal ATPases likely involved in copper/metal homeostasis (Tamayo *et al.*, 2014).

ABC transporters

The first ABC transporter described in the Glomeromycotina was GintABC1, an ortholog of the yeast cadmium factor (ycf1) that transports metal-glutathione complexes into the vacuoles and that was suggested to play a role Cu and Cd tolerance in *R. irregularis* (González-Guerrero *et al.*, 2010). Thirty-one more genes putatively encoding ABC transporters were identified in the *R. irregularis* transcriptome. They include ABC multidrug transporters, multidrug resistance-associated proteins, MRP-like ABC transporters and oligomycin resistance ATP-dependent permeases.

Transporters of Macronutrient Ions

Phosphate transporters

Improved phosphorus uptake is the main benefit of the AM symbiosis for the host plant. The first step of symbiotic phosphorus uptake is phosphate uptake from the soil by the extraradical mycelium, which is believed to occur through by a phosphate/proton symporter of the *S. cerevisiae* Pho84 family. Phosphate transporters have been described in *D. epigaea* (Harrison and van Buuren, 1995), *F. mosseae* (Benedetto *et al.*, 2005), *R. irregularis* (Maldonado-Mendoza *et al.*, 2001) and *G. margarita* (Xie *et al.*, 2016). These transporters are expressed in the extraradical mycelium, suggesting a role in phosphate uptake from the soil. However, this hypothesis has not been proven due to the lack of stable transformation systems for AM fungi. By using yeast as a heterologous expression system, it was shown that the *D. epigaea* and *G. margarita* phosphate transporters *GvPT* and *GigmPT* encode high-affinity transporters that are dependent on the metabolic energy generated by the H^+ -ATPase. These transporters are also expressed in the intraradical mycelium suggesting a second role in phosphate reabsorption from the apoplast of the symbiotic interface created in the arbuscule-colonized cortical cells (Benedetto *et al.*, 2005). Inactivation of *GigmPT* by host-induced gene silencing impaired arbuscule development, supporting the view that phosphate itself acts as a signal in the establishment of the symbiosis and that *GigmPT* is a transceptor that is involved both in P_i transport and P_i sensing (Xie *et al.*, 2016).

The *R. irregularis* genome also has homologs of the *S. cerevisiae* Na^+ /phosphate symporter Pho89p and of the low-affinity vacuolar phosphate transporter Pho91 (Tisserant *et al.*, 2012). However, these transporters have not been characterized yet.

Ammonium transporters

Two high-affinity ammonium transporters, GintAMT1 (López-Pedrosa *et al.*, 2006) and GintAMT2 (Pérez-Tienda *et al.*, 2011), and one low-affinity GintAMT3 (Calabrese *et al.*, 2016) have been characterized in *R. irregularis*. GintAMT1 is highly expressed in the extraradical mycelium and is believed to mediate soil NH_4^+ uptake when NH_4^+ is present in low concentrations, for example, in acidic conditions. However, GintAMT2 might be involved in the recovery of NH_4^+ leakage during fungal metabolism, as it is highly expressed in the arbuscules. Finally, the low-affinity ammonium transporter GinAMT3, which is also expressed in the

arbuscules, could be also involved in NH_4^+ retrieval from the symbiotic interface but when the NH_4^+ concentrations are high. Both the high-affinity and low-affinity NH_4^+ transport processes require metabolic energy provided by the plasma membrane H^+ -ATPase, as both transport activities were inhibited when the extraradical mycelium was supplied with the ionophore carbonylcyanide *m*-chlorophenylhydrazone and the ATP-synthesis inhibitor 2,4-dinitrophenol (Pérez-Tienda *et al.*, 2012). Orthologs of the *R. irregularis* AMT genes have been identified in the genomes of *G. rosea*, *G. margarita*, and *D. epigaea*, but they have not been characterized yet.

Nitrate transporters

Although AM fungi show a clear preference for NH_4^+ they are also able to take up nitrate (Villegas *et al.*, 1996). Only a high-affinity nitrate transporter (GiNT) has so far been partially characterized in *R. irregularis* (Tian *et al.*, 2010). A role for GiNT in transporting nitrate into the extraradical mycelium was suggested, as its expression is regulated by nitrate availability.

Other transporters of inorganic ions

Despite several studies have shown the ability of AM fungi to improve potassium or sulfur nutrition of their host plants (Smith and Read, 2008), the fungal transporters involved in the symbiotic transport process of these nutrients have not been described yet. Genes encoding putative potassium transporters of the Trk (acronym of transport of K) and HAK (high-affinity K uptake) families and sulfate transporters have been identified in the genomes of the sequenced AM fungi. However, further research is needed to elucidate their role in the mycorrhizal transport pathway of these macronutrients.

Metal Transporters

Metal ions are essential micronutrients for fungal metabolism, as they are essential components of a wide variety of metallo-proteins, transcription factors, and other proteins. Fungi possess a repertoire of metal transport proteins mediating active uptake of metals when present at low concentrations (Radisky and Kaplan, 1999) and intracellular transport systems delivering metals to the different organelles (Luk *et al.*, 2003). However, high metal ion concentrations are toxic. Under these conditions, transport systems pumping metals out of the cytosol and compartmentalizing excess metal in the vacuoles contribute to metal detoxification (Ruotolo *et al.*, 2008). The importance of metal transporters in AM fungi relies not only on their role on AM fungal homeostasis but also on the importance of these fungi on host plant homeostasis (Ferrol *et al.*, 2016). In fact, AM fungi increase the uptake of low mobility metal micronutrients when plants grow in soils deficient in these elements and, on the other hand, to alleviate metal toxicity in contaminated soils. Several genes putatively encoding proteins implicated have been identified in the genomes of the sequenced AM fungi and mined in the genome of *R. irregularis* (Tamayo *et al.*, 2014).

Zinc transporters

Two families of Zn transporters have been described in *R. irregularis*: the ZIP and the CDF families. The *R. irregularis* ZIP family is composed of five members that, although have not been characterized yet, are likely involved in transport of Zn and/or other metal ion substrates from the extracellular space or organellar lumen into the cytoplasm. In contrast, CDF proteins transport Zn and/or other metal ions from the cytoplasm into the lumen of intracellular organelles or to the outside of the cell (Eide, 2006). Out of the six genes potentially encoding CDF transporters in *R. irregularis* only *GintZnT1* has been functionally characterized (González-Guerrero *et al.*, 2005). *GintZnT1* was shown to be involved in Zn detoxification, as its expression in yeast decreased Zn cytosolic levels and its expression pattern in response to Zn correlated with the accumulation pattern of Zn in the fungal vacuoles.

Copper transporters

The *R. irregularis* genome has two genes encoding Cu transporters of the Ctr family and a CTR-like protein (Gómez-Gallego *et al.*, 2019). Members of this family mediate Cu^+ uptake by a passive, membrane potential-dependent mechanism. Functional analyses in yeast and gene expression patterns in response to copper revealed that *RiCTR1* encodes a plasma membrane Cu transporter that is involved in Cu uptake by the extraradical mycelium and *RiCTR2* a vacuolar transporter involved in Cu mobilization of vacuolar stores. The third gene *RiCTR3* produces, as a consequence of an alternatively spliced event, two transcripts, *RiCTR3A* and *RiCTR3B*. *RiCTR3B* was suggested to be a receptor involved in Cu tolerance, as it confers copper tolerance to the metal sensitive $\Delta yap-1$ mutant yeast and its expression is highly induced by Cu toxicity in the extraradical mycelium (Gómez-Gallego *et al.*, 2019).

Iron transporters

Three members of the reductive pathway of Fe assimilation, the ferric reductase (RiFRE1) and the high-affinity Fe permeases (RiFTR1–2), have been characterized in the model fungus *R. irregularis* (Tamayo *et al.*, 2018). In this high-affinity uptake process, the metal is reduced from Fe^{3+} to Fe^{2+} by membrane-bound ferrireductases, and then it is rapidly internalized by the concerted action of a ferroxidase and a permease that form a plasma membrane protein complex (Kwok *et al.*, 2006). Functional analyses in yeast mutants and gene expression patterns in response to Fe indicate a role for the plasma membrane RiFTR1 in Fe acquisition by both the extraradical and intraradical mycelium and for RiFTR2 in Fe homeostasis under Fe-deficient conditions.

Arsenite efflux pump

Although specific transporters for non-essential metals, such as arsenate, unlikely exist in AM fungi, uptake of these non-essential and toxic metals is mediated by transporters of essential metals or even through other type of transporters. For example, in *R. irregularis* uptake of the metalloid arsenate occurs via the high-affinity phosphate transporter GiPT (González-Chávez *et al.*, 2011). However, arsenite detoxification is partially mediated via the specific efflux pump of arsenite GiArsA (González-Chávez *et al.*, 2014).

Transporters of Organic Compounds**Organic nitrogen transporters**

Besides inorganic nitrogen, AM fungi can take up from the soil organic nitrogen in the form of amino acids, such as glycine, glutamic acid and arginine, and in the form of small peptides (Hawkins *et al.*, 2000). So far, an amino acid permease (GmosAPP1) and a dipeptide transporter (RiPT2) have been characterized in *F. mosseae* and *R. irregularis*, respectively. GmosAPP1 is expressed in the extraradical mycelium and transports non-polar and hydrophobic amino acids, such as proline, serine, glycine, and glutamine, by a proton-coupled, pH and energy-dependent process (Cappellazzo *et al.*, 2008). The *R. irregularis* dipeptide transporter RiPTR2 is expressed both in the extraradical and intraradical mycelium and has been suggested to play a role in the uptake of small peptides from the soil and the reuptake of peptides from the interfacial apoplast (Belmondo *et al.*, 2014). As yet uncharacterized oligopeptide transporter was also found to be overexpressed in the intraradical mycelium of *G. rosea* (Tang *et al.*, 2016).

Sugar transporters

As obligate biotrophs, AM fungi need the supply of carbon compounds from the host plant for their growth and metabolism. Based on stable isotope labeling experiments, it has long been considered that AM fungi receive carbohydrates and specifically glucose from the plant (Pfeffer *et al.*, 1999; Trepanier *et al.*, 2005). However, it has been recently shown that despite lipids comprise up to 95% of spore dry weight (Bécard *et al.*, 1991) and up to 47% of hyphal volume in some regions of the extraradical mycelium (Bago *et al.*, 2002), AM fungi are auxotrophs for fatty acids and they also receive lipids from the plant host (Bravo *et al.*, 2017; Jiang *et al.*, 2017); however, the fungal transporter mediating lipid uptake remains uncharacterized.

Sugar uptake from the apoplast of the symbiotic interface created in the arbuscule-colonized cortical cell is mediated in *R. irregularis* by the monosaccharide transporter RiMST2 (Helber *et al.*, 2011). RiMST2 is a high-affinity monosaccharide transporter that operates by a H⁺ cotransport process with a broad substrate spectrum. Besides glucose, it is able to transport xylose, mannose, and fructose with decreasing affinity in that order. RiMST2 is primarily expressed in intraradical fungal structures, and its silencing results in impaired formation, malformed arbuscules. Additional monosaccharide transporters (RiMST3, RiMST4, RiMST5 and RiMST6) and a putative sucrose transporter (RiSUC1) have been identified in *R. irregularis* (Helber *et al.*, 2011). However, their contribution to sugar uptake has not been clarified yet.

Water Channels

Aquaporins have been functionally characterized in *R. irregularis* and *R. clarus*. In *R. irregularis*, the two identified aquaporins RiAQP1 and RiAQP2 were found to be expressed both in the extraradical mycelium and in the arbuscules (Li *et al.*, 2013). Three genes potentially encoding aquaporins have been identified in *R. clarus*. RAQP3 aquaporin 3 was most highly expressed in intraradical mycelia and encodes an aquaglyceroporin responsible for water transport across the plasma membrane. Knockdown of RAQP3 by virus-induced gene silencing revealed a role for this water channel in phosphate translocation from the outer to the inner hyphae (Kikuchi *et al.*, 2016).

Concluding Remarks

During the last decades research on membrane transport has made continuous progress and still remains an active field of study. A tremendous number of integral membrane proteins have been characterized in different fungi, especially in the model yeast *S. cerevisiae*, and the mechanisms by which their function is regulated have been elucidated.

Despite nutrient transport has been one of the more extensively studied aspects of the AM symbiosis; current knowledge on AM fungal transporters is still in its infancy. Significant progress has been made recently through the release and subsequent mining of genome sequences. The repertoire of annotated genes potentially encoding membrane transport proteins represents valuable sequence data for further functional validation. *S. cerevisiae* has been shown to be a useful tool to determine the function of the AM fungal transporters identified so far. Although AM fungi can not be genetically modified, development of host-induced and virus-induced gene silencing techniques of AM fungal genes has allowed functional analysis of a few genes expressed in the intraradical mycelium. It is expected that developments and advances in technologies, such as – omics, live cell imaging, stable isotope tracking and genetic manipulation, will provide a holistic view of the transport systems operating in AM fungi. This knowledge will be crucial to understand their biology and adaptation to environmental stresses.

Introduction

Primary metabolism is referred to the biochemical reactions that lead to metabolites which are required for the growth and maintenance of cellular functions. These natural compounds are the precursors for the formation of essential biomolecules such as nucleic acids, proteins, carbohydrates and lipids. Vital primary metabolism is related with the phase of rapid microbial growth, the so-called logarithmic growth phase. A maximum accumulation of primary metabolites is present at the end of that phase, while in the following stationary phase the metabolites derived from primary metabolism may be further transformed to other products including secondary metabolites (SMs).

SMs are low molecular-weight compounds derived from primary metabolites via specialized pathways. They are produced mainly by microorganisms and plants, typically only by a limited range of species (Vinale *et al.*, 2009).

The fungi produce a huge number and variety of SMs, many of which have interesting biological activities. They serve important functions such as: (1) competitive weapons against bacteria, fungi, plants, insects and animals; (2) metal transporting agents; (3) agents of symbiosis between microbes and plants, nematodes, insects, etc.; (4) sexual hormones (Demain and Fang, 2000).

SMs are not essential for vegetative growth in pure culture but are commonly obtained during the stationary phase, which is often related to differentiation and sporulation. Batch rather than continuous culture usually favors secondary metabolite production (Demain and Fang, 2000).

These natural compounds show an enormous variety of structures and biosynthetic origins, and there have been many examples of SMs with chemical features previously unreported. Moreover, the production is limited to one or a few organisms, which may not be closely related, and it differs significantly among diverse strains of the same species (Herbert, 1994).

Fungi have been exploited to yield various SMs useful for application and subsequent production of valuable supplies such as antibiotics, vitamins, pharmaceutical compounds, fungicides, plant growth regulators, and hormones. Fungal SMs used in medicine include the cyclosporines (immunosuppressants) from *Tolypocladium inflatum*, the cholesterol-reducing compound lovastatin, produced by *Aspergillus terreus* and the antibiotic penicillin biosynthesized by *Penicillium chrysogenum*. *Gibberella fujikuroi* releases gibberellins, that are plant hormones also known as virulence factor of this fungus on plants. Although interest in these beneficial metabolites is significant to humankind (in medicine, industry and agriculture), fungi also produce deleterious SMs with toxic effects (e.g., mycotoxins) (Demain and Fang, 2000). These include the cytotoxic and antiproliferative aspyridones from *Aspergillus nidulans*, the aflatoxins produced by *Aspergillus flavus*, and gliotoxin produced by *Aspergillus fumigatus*, for which toxicity has been ascribed to a disulfide bridge present in this metabolite (Brakhage, 2013).

Many examples of fungal metabolites with toxic effects (mycotoxicosis) on animal organisms have been reported in the veterinary literature. Starting from 1970 several cases have been recorded and these findings made a major impact on the scientific community, resulting in the present concern about the effects of mycotoxins on human health (Campbell and Stoloff, 1974; Marroquín-Cardona *et al.*, 2014). Aflatoxins, ochratoxins, fumonisins, deoxynivalenol, and zearalenone are the major mycotoxins in terms of public health concern. These fungal metabolites can cause adverse effects in humans and due to the cosmopolitan nature of mycotoxigenic fungi contribute to the worldwide incidence of mycotoxins in food and feed (Lee and Ryu, 2017).

Biochemistry and Biological Impact of Fungal Secondary Metabolites

Fungal SMs are formed as families of closely related compounds resulting from biosynthetic enzymes less specific to their substrate than those of primary metabolism (Hanson, 2003). The yield of different family members can be modified by changing the composition of the growth medium, the environmental conditions and by mimicking biotic interactions (i.e., co-cultures) (Vinale *et al.*, 2017; Pan *et al.*, 2019). Different members of a family frequently demonstrate diverse biological activities (Hanson, 2003).

The majority of SMs belong to one of the following families: (1) Polyketides and fatty acids; (2) Terpenoids and steroids; (3) Phenylpropanoids; (4) Alkaloids; (5) Specialized amino acids and peptides (Hanson, 2003).

Though not crucial for their survival, fungi bio-synthesize numerous SMs of the mentioned families with different chemical structures and properties. Especially filamentous Asco- and Basidiomycota are rich sources of polyketides, non-ribosomal peptides, terpenes and indole alkaloids that are biosynthesized via specialized pathways (Herbert, 1994).

Fungal secondary metabolism often is connected to specific stages of morphological differentiation such as asexual sporulation. The produced SMs are incorporated into structural elements of the cell or released into the environment as volatiles or dissoluble substances. They hence play important roles in regulating interactions between organisms. Examples of fungal compounds involved in biotic interactions are phytotoxins, produced by fungal pathogens as virulence factors for plants, mycotoxins,

produced during the colonization of crops by specific fungi and capable of causing disease and death in humans and other animals, pigments, with antioxidant activity, and antibiotics, that are considered natural products capable of killing or inhibiting microbes. It is important to underline that biological activities are not essentially limited to one specific group or single metabolites and a single fungal metabolite can produce different effects on specific targets (Karlovsky, 2008).

Antibiotics are produced by fungi for gaining an advantage in competition, permitting the microbe to occupy space and to acquire access to nutrients. Most of the useful fungal SMs have been isolated and characterized via a screening approach following “bioassay-guided fractionation”, meaning that the bioactivity of the compound(s) are constantly monitored during the isolation procedure by employing *in vitro* or *in vivo* test systems for detecting the biological activity of an extract or a pure substance (bioassay). All generated fractions are tested for biological activity, and those showing the desired bioactivity are further processed until the bioactive compound is obtained in a pure form (Ghisalberti, 2003; Colegate and Molyneux, 2007).

Main Classes of Fungal Secondary Metabolites

Polyketides

Polyketides are the amplest class of fungal SMs and are biosynthesized by type I polyketide synthases (PKSs). Short-chain carboxylic acids, typically acetyl-coenzyme A (acetyl-CoA) and malonyl-CoA, are condensed to form carbon chains of variable lengths. The main difference between polyketides and fatty acids is the full reduction of the β -carbon in fatty acids, which is an optional event in polyketide synthesis. The variety of fungal polyketide chemical structures is a consequence of many iteration reactions, the number of reduction reactions, which extender unit is used and, in the case of aromatic polyketides, cyclization of the nascent polyketide chain. Other structures are related to the introduction of diverse post-polyketide-synthesis steps.

Non-ribosomal peptides

Non-ribosomal peptides may contain non-proteinogenic amino acids and are synthesized by enzymes named non-ribosomal peptide synthetases (NRPSs). The diversity among non-ribosomal peptides depends on the number of amino acids (peptide length), if the peptide is cyclized, and variations in the functions of the NRPS domains.

Terpenes and terpenoids

Terpenes are linear or cyclic compounds composed of isoprene units which can be saturated or unsaturated, and modified in various ways. Terpenoids are derivatives of terpenes that contain additional functional groups and oxidized methyl groups moved or removed at various positions. Terpenoids are divided into monoterpenes, sesquiterpenes, diterpenes, sesterpenes, and triterpenes depending on their carbon units. Monoterpenes are produced from geranyl pyrophosphate, sesquiterpenes are generated from farnesyl pyrophosphate, and diterpenes and carotenoids are biosynthesized from geranylgeranyl pyrophosphate. The defining enzyme in terpene biosynthesis is terpene cyclase, which generates different terpenes from different diphosphates.

Indole alkaloids

Indole alkaloids are typically resulting from tryptophan and dimethylallyl pyrophosphate. Occasionally other amino acids than tryptophan are used as precursors (Keller *et al.*, 2005).

The overall pathway of carbon from sugars up to the formation of the main classes of fungal SMs is given in Fig. 1. In particular, it is possible to follow the biosynthetic relationship of these natural products (Hanson, 2003).

Biological Functions and Ecological Roles of Fungal Secondary Metabolites

SMs can provide self-protection, they may act as mediators for communication with other organisms and are virulence factors for plant and animal pathogens. Moreover, they serve as defense molecules against other microbes (antibiotics) thus contributing to the organization of microbial consortia.

The role of fungal SMs in microbial interactions is mainly referred to the production of antibiotics, recognized as weapons to kill or inhibit competitors. For example, penicillin was discovered for the antibiosis of *Penicillium* spp. contaminating *Staphylococcus* spp. Recently their function as signaling molecules in microbial consortia has been demonstrated and several microorganisms have established diverse mechanisms to cope with antimicrobial molecules produced by antagonists. Moreover, some antibiotics also promote the growth of other microbes, act as chemoattractants, or function in a specific communication process (quorum sensing, with the secretion of virulence factors and/or biofilm formation). Another example is that production of 2,4-diacetylphloroglucinol, a specific antibiotic released by *Pseudomonas fluorescens*, is reduced by fusaric acid formed by *Fusarium oxysporum* through repression of the responsible biosynthetic genes. In contrast, fusaric acid and other metabolites promote the colonization of *F. oxysporum* hyphae by *P. fluorescens* (Fox and Howlett, 2008).

Some examples of fungal SMs are given in Fig. 2.

Close physical interactions among fungi and bacteria results in a specific regulation of fungal secondary metabolism that may increase or decrease the production of specific molecules. In some cases, these interactions may also induce the *ex-novo* production of a single metabolite (i.e., the production of orsellinic acid-derived polyphenols by *Aspergillus nidulans*) (Kusari *et al.*, 2012).

Fig. 1 Biosynthetic relationship of fungal secondary metabolites. The main classes of fungal secondary metabolites are given in bold. Acetyl Co-Enzyme A is the molecule from which the main metabolites are derived.

SMs help fungi to be competitive in an ecological niche. In this context it is important to underline that the effects of natural products are depending on the ecological concentrations and a single metabolite can function as a signal rather than as a toxin. Gradient-dependent effects of phenazine from *Pseudomonas aeruginosa* on *Aspergillus* spp. have been demonstrated. A high concentration of this compound is antibiotic while a low to moderate concentration induces sporulation in the fungus. Many examples of induction of fungal SMs when fungi are confronted by other microbes are reported in literature that represent a sort of microbial 'language' (Keller, 2019).

Dose-effect responses of fungal metabolites on plant growth and development have also been recognized. This is the case for some *Trichoderma*-derived SMs (i.e., 6-pentyl- α -pyrone, harzianolide, harzianic acid) that may act as auxin-like compounds. Typically, these molecules have an optimum activity among 10^{-5} and 10^{-6} M while are inhibitory at higher concentrations (Vinale *et al.*, 2008; Vinale and Sivasithamparam, 2020).

SMs are further known as virulence factors in plant-fungal interactions and their role in the interaction with animals is also recognized, although not completely elucidated. Moreover, fungal metabolites are involved in the interactions of symbiotic and mycorrhizal or endophytic fungi with plants.

The communication with insects also elicits biosynthesis of SMs in fungi. This interaction is well described in entomopathogenic fungi, especially in *Metarhizium* spp., *Beauveria bassiana* and *Pochonia* spp. Examples of such compounds are destruxins, a cyclic depsipeptide from *Metarhizium anisopliae* with different modes of actions (i.e., inhibiting V-ATPase, changing ion transport in gut and epithelial tissues, even making behavioral changes), tenellin, beauvericin, and bassianolide from *B. bassiana*.

Fungal Genes Involved in Secondary Metabolite Biosynthesis

Most of the core genes coding for enzymes that act in a discrete pathway for the biosynthesis of a specific secondary metabolite are located in physical vicinity in the fungal genome. This grouping of functionally linked genes into biosynthetic gene clusters (BGC) is a distinctive feature of fungal secondary metabolism.

The central part of a secondary BGC typically codes for a backbone-generating enzyme such as polyketide synthase (PKS), non-ribosomal peptide synthetase (NRPS), hybrid NRPS-PKS, dimethylallyl tryptophan synthase, or terpene cyclase. PKS and NRPS core enzymes consist of multiple domains that progressively assemble the metabolite backbone. Their genes show high diversity and discontinuous distribution across fungal genomes, respectively, and evolve rapidly. In addition, accessory enzymes involved in chemical modification of the generated product to generate the final compound, transporters for product export, and transcription factors for cluster regulation may be encoded by cluster-resident genes (Fig. 3). Although secondary BGC often are self-contained units for the biosynthesis of a specific substance, this is not necessarily always the case. There is no standard composition of these gene clusters but diversity regarding structure, content and size even among different strains of the same fungal species. Some clusters for example encode multiple backbone genes while others lack certain genes such as those coding for transcription factors that regulate biosynthetic gene expression. The penicillin biosynthesis cluster of *Penicillium chrysogenum* exemplifies the latter case.

Fig. 2 Examples of fungal secondary metabolites belonging to the main groups of natural products. Polyketides: (1) Mellein from *Aspergillus melleus*; (2) Griseofulvin from *Penicillium griseofulvum*; (3) Patulin from *Penicillium* spp.; (4) 6-pentyl- α -pyrone from *Trichoderma* spp.; (5) 1-hydroxy-3-methyl-anthraquinone from *Trichoderma harzianum*; (6) Aflatoxin B1 from *Aspergillus flavus*. Terpenes and terpenoids: (7) T2 Toxin from *Fusarium* spp.; (8) Gibberellin GA3 from *Gibberella fujikuroi*; (9) Deoxynivalenol from *Fusarium* spp. Non-ribosomal peptides: (10) Gliotoxin from *Trichoderma* and *Gliocladium* spp.; (11) Alametecin, from *Trichoderma viride*. Indole alkaloids: (12) Ergotamine from *Claviceps purpurea*; (13) Fumitremorgin C from *Aspergillus fumigatus*.

Fig. 3 Scheme of a prototypical secondary metabolism gene cluster and its subtelomeric localization on the chromosome.

A pathway-specific regulator is absent from the gene cluster; instead, penicillin production is subject to regulation by a network of global regulatory proteins that are responding to diverse nutritional and environmental cues and simultaneously govern various cellular processes including metabolism and development. The biosynthesis of a given secondary metabolite may also involve more than one gene cluster. This is the case for cephalosporin production by *Acremonium chrysogenum*, to which two clusters are contributing (Martin *et al.*, 2014; Zeilinger *et al.*, 2015).

A further hallmark of many fungal secondary BGC is their enrichment near to the ends of chromosomes, at subtelomeric regions. As the areas adjacent to the telomeres contain densely packed nucleosomes which renders them transcriptionally silent, these secondary BGC are subject to chromatin-level control. Nucleosome repositioning as well as DNA and histone modifications are involved in their transcriptional activation, which occurs in response to pleiotropic environmental triggers (Collemare and Seidl, 2019).

Besides impacting their expression, the subtelomeric localization of secondary BGC is believed to affect evolution and horizontal gene transfer as these regions usually are highly prone to recombination. While gene duplication had a prominent role in the evolution and subsequent diversification of secondary metabolic genes, several BGC seem to have originated from the horizontal transfer of genes from bacteria to fungi. The clustering of secondary metabolism genes then further facilitates their intra-kingdom horizontal transfer between different fungal species and contributes to metabolic diversity (Osbourne, 2010).

The metabolic potential of a given fungus can be explored directly from its genome sequence by screening for backbone genes and gene clusters using bioinformatics approaches. Among the different groups of fungi, filamentous ascomycetes are especially rich in secondary metabolism BGC. In these organisms, which typically harbor dozens of these clusters, a significant portion of their genome is devoted to secondary metabolite biosynthesis and its regulation. However, many gene clusters for secondary metabolism pathways are unexpressed and hence no product is present under standard laboratory culture conditions, as these do not mimic the required physiological triggers the producing fungus encounters in its natural habitat. The activation of these unexpressed BGC is a promising avenue to further exploit fungi as a source of bioactive natural products, including novel drug leads. Hitherto successful approaches tackled cluster composition and regulation by using genetic engineering, chromatin structure modification by using epigenetic modifiers, as well as simulation of the natural habitat by using co-cultivation and synthetic microbial communities (Keller, 2019).

Regulation of Fungal Secondary Metabolism

Fungal secondary metabolism is regulated by a complicated network of signals, some of them activated as a response to particular nutritional or environmental conditions, and that usually affect in a wider form to the fungal metabolism, not specifically to the secondary metabolism (Fig. 4) (Brakhage, 2013; Keller, 2019; Macheleidt *et al.*, 2016; Yin and Keller, 2011).

The New Generation Sequencing and Bioinformatic techniques/tools currently available emphasize the potential of fungi to produce an enormous variety of secondary metabolites. However, it has been also shown that for a particular growth and/or environmental condition only a minimal fraction of the BGC identified on a fungal genome are expressed and their products detected, remaining the rest in a cryptic or quasi-cryptic state.

Pathway-Specific Regulators

Pathway-specific regulator genes are usually located inside the BGC, or at least in one of the clusters of genes involved in its biosynthesis. The most common transcription factors (TF) regulating fungal SMs production are those of the Zn_2Cys_6 (=C6-Zn) binuclear type, but Cys_2His_2 Zinc finger TFs are also common, even when they are less known (Fig. 4). Other, less frequent TFs in fungi are basic region leucine zipper (bZIP) and winged helix proteins. bZIP are involved in stress response and regulation of SM biosynthesis (Shaaban *et al.*, 2010), and winged helix TFs, have been related to the production of cephalosporin C in *A. chrysogenum* (Schmitt and Kück, 2000).

Fig. 4 Main Pathway specific (upper panel) and Global (lower panel) regulation protein-complexes involved in regulation of secondary metabolism. Thick blue arrow in the upper panel corresponds to a gene encoding a pathway specific regulator inside the biosynthetic gene cluster (BGC). Red arrow represents a gene encoding one of the key enzymes usually found in the secondary metabolite BGCs, i.e., PKS, NRPS, hybrid PKS-NRPS, terpene synthase. In the upper panel, dashed lines indicate the possibility that one particular pathway specific regulator would have a more global effect, regulating other secondary metabolite (SM) BGCs and also eventually some genes involved in primary metabolism. P = Promoter region.

C6-Zn TFs recognize palindromic motifs in BGC promoters (Fernandes *et al.*, 1998). Nowadays, there are known many of these regulators, being some of the most studied examples: AflR from *Aspergillus* species, which is involved in the biosynthesis of sterigmatocystin/aflatoxin (AF/ST) (Chang *et al.*, 1995); GliZ for regulation of gliotoxin biosynthesis in *A. fumigatus* (Bok *et al.*, 2006), LovE for lovastatin biosynthesis regulation in *A. terreus*, FUM21 for fumonisin biosynthesis regulation in *Fusarium verticillioides* (Brown *et al.*, 2007), and AfoA for regulation of asperfuranone in *A. nidulans* (Grau *et al.*, 2018) (Fig. 4). These TFs are usually required for expression of most, if not all, the other genes involved in the SM biosynthesis. For example, in the gliotoxin biosynthesis, all the genes present in the BGC, except *gliT*, are regulated by GliZ. GliT, is a gliotoxin oxidase, which confers resistance to gliotoxin (Schrettl *et al.*, 2010).

A recently reported exception to these C6-Zn TFs is Tri21. Its encoding gene is present in one of the *TRI* BGCs in species belonging to the *Fusarium incarnatum-equiseti* species complex (FIESC). Tri21 regulates only the late genes involved in the biosynthesis of the trichothecene deacetoxyscirpenol (Brown *et al.*, 2020).

Cys_2His_2 Zn finger proteins constitute the other main type of fungal pathway-specific regulators. Some examples are: Tri6 (Proctor *et al.*, 1995), involved in regulation of trichothecene mycotoxins biosynthesis; ToxE for production of HC-toxin, a cyclic tetrapeptide, in *Cochliobolus carbonum* (Pedley and Walton, 2001), and ScpR, involved in synthesis of asperfuranone in *A. nidulans* (Bergmann *et al.*, 2010) (Fig. 4). Tri6 is an unusual zinc finger protein that regulates all genes involved in trichothecene biosynthesis and transport. However, its effect is not restricted to genes belonging to trichothecene BGCs. In *F. graminearum* Tri6 behaves, at least in some physiological conditions, more as a global regulator than as a pathway specific TF. This conclusion was supported by the description that more than 20% of the genes in the genome of *Trichoderma arundinaceum* were negatively regulated in a *tri6*-deletion background (Lindo *et al.*, 2018). Furthermore, Tri6 also acts as an autoinducer, and requires for wild-type expression of *TRI* genes a second regulator, Tri10, whose encoding gene is also located in one of the trichothecene BGC.

Regulation of Secondary Metabolism by Nutritional and/or Environmental Conditions

pH regulation

The global regulator PacC/RIM101/PAC-3/Pac1 is a Cys₂His₂ zinc finger transcription factor that is processed to its mature form only at alkaline pH (Peñalva *et al.*, 2008). PacC positively regulates the expression of all three structural genes involved in penicillin biosynthesis at alkaline pH. PacC was reported to regulate also other diverse SM biosynthetic pathways in other fungi, e.g., it negatively regulates the expression of genes involved in sterigmatocystin biosynthesis in *A. nidulans* (Keller *et al.*, 1997).

Regulation by carbon and nitrogen sources

Presence of easily assimilable carbon sources usually results in a repression of a wide variety of genes in fungal BGCs. In these conditions fungal growth prevails versus differentiation and production of SM. This mechanism, known as carbon catabolite repression, is mediated by CreA. This TF possesses a single Cys₂Cys₂ GATA Zn finger module, and was first described in *A. nidulans* (Dowzer and Kelly, 1991), but homologs have been identified in a wide diversity of fungi, including *A. flavus*, *A. fumigatus*, *A. niger*, *A. oryzae*, *A. chrysogenum* (*cre1*), *Candida albicans* (*Mig1*), *Cryptococcus neoformans*, *Saccharomyces cerevisiae* (*Mig1p*), and *Trichoderma reesei* (*Cre1*), as representative examples (Fig. 4).

Some of the SMs whose biosynthesis is known to be repressed by CreA include cephalosporin and penicillins in *A. chrysogenum* and *Penicillium chrysogenum* or *A. nidulans*, respectively (Martín *et al.*, 1999; Espeso and Peñalva, 1992). The reduction in production of these antibiotics, mediated by CreA was observed by a down-regulation of all genes involved in penicillin biosynthesis, i.e., *pcbAB*, *pcbC*, *penDE*, in *P. chrysogenum*, or *pcbC* and *cefEF* genes for cephalosporin biosynthesis in *A. chrysogenum* in the presence of glucose (Gutiérrez *et al.*, 1999; Jekosch and Kück, 2000).

Regulation of SM production by the nitrogen source is mediated by the global nitrogen regulator AreA (Fig. 4), which is also a Cys₂His₂ Zn finger TF that mediates nitrogen repression in response to NH₄⁺ or glutamine levels (Wilson and Arst, 1998). AreA is responsible for nitrogen-mediated repression of the gibberellin BGC in *F. fujikuroi* (Tudzynski *et al.*, 1999), and in the opposite it is required for the production of fumonisin B1 in *F. verticillioides* (Kim and Woloshuk, 2008). In a recent study, a genomic approach led to identify at least 4 NRPS, 3 PKS and 4 terpene synthases, involved in the synthesis of six different SM (ferrichrome, beauvericin, fusarins, fumonisins, gibberellins, acorenol), whose biosynthesis might be regulated by AreA in *F. fujikuroi* (Janevska and Tudzynski, 2018), thus emphasizing the general role of AreA in fungal SM BGC regulation.

Redox status and iron levels

The ability to maintain redox balance and iron homeostasis is crucial to all organisms. The CCAAT-binding complex (CBC) consists of three subunits, named HapB, HapC, and HapE in *A. nidulans* (Fig. 4), which are responsible for DNA binding, and is described as involved in sensing of reactive oxygen species (ROS) through oxidative modifications of cysteine residues of the HapC component, and hence represent a major mechanism of redox regulation (Hostschansky *et al.*, 2007). Furthermore, oxidation of these cysteines blocks CBC assembly. This complex would have a general regulatory role independent of the iron status, positively regulating utilization of nitrogen and carbon sources, and production of SMs such as penicillin in *A. nidulans* (Brakhage *et al.*, 1999), and aflatoxins in *A. parasiticus* (Reverberi *et al.*, 2008).

Iron is an essential cofactor for multiple cellular processes, e.g., respiration, biosynthesis of amino-acids, synthesis of sterols. However, excess of iron can potentially catalyze formation of ROS. Thus, iron levels must be tightly regulated. For sensing iron levels, a fourth peptide, HapX (Fig. 4), interacts with CBC complex in iron starvation conditions. Binding of HapX to CBC results in transcriptional repression of iron-dependent pathways and activation of the siderophore system to increase iron acquisition, such as siderophore biosynthesis (Hostschansky *et al.*, 2007). A repression of ergosterol biosynthetic genes by CBC complex has been also described in *A. fumigatus* in iron starvation conditions, which correlates with the high demand for heme-bound iron as a cofactor for ergosterol biosynthesis. Note that a huge number of fungal SMs require intermediates of the ergosterol biosynthetic pathway as precursors for their biosynthesis, e.g., sesquiterpenes, triterpenes, etc.

Regulation Mediated by Chromatin Modifications

Histone methylation

LaeA/LAE1 (loss of *afIR* expression A) is a nuclear methyltransferase-domain containing protein that interacts with VeA and VelB to form the velvet heterotrimeric complex. This complex synchronizes secondary metabolism and fungal development in relation to the light levels. LaeA is a global regulator of fungal secondary metabolism that was firstly described in the genus *Aspergillus*. It is required for the biosynthesis of several SM in different species of this genus, e.g., sterigmatocystin, penicillin, gliotoxin, terre-quinose A, lovastatin, aflatoxin, mycelial pigments,... (Bok and Keller, 2004), but also in other fungal species, e.g., *Alternaria alternata* (Estiarte *et al.*, 2016), *Monascus ruber* (Liu *et al.*, 2016), *A. fumigatus* (Perrin *et al.*, 2007), *A. niger* (Wang *et al.*, 2018), and *F. verticillioides* (Butchko *et al.*, 2012). Light blocks the formation of the velvet complex, then repressing velvet-dependent functions, such as those related with secondary metabolism (Brakhage, 2013).

The sequence similarity of LaeA to histones and arginine methyltransferases, together with the analysis of mutants in genes encoding for the later enzymes, reveal that expression of SM genes should be related with the removal of heterochromatin marks in the genomic regions where these BGCs are located (Yin and Keller, 2011) (Fig. 5). Thus, the effect of LaeA, and hence of the velvet complex, is associated with chromatin modifications that would counteract the establishment of heterochromatin marks, i.e.,

Fig. 5 Regulation of secondary metabolite BGC expression mediated by chromatin modifications. Complexes/proteins involved in that regulation are shown. Those marks and enzymes related to heterochromatin (non-expressed BGCs) or euchromatin (expressed BGCs) are written in red and green, respectively. H3K9me= methylation of lysine 9 (K9) in histone 3 (H3); H3K4me, me2, me3= mono, di-, and tri-methylation of lysine 4 in histone 3; H3K9ac and H3K14ac= acetylation of lysine 9 and lysine 14, respectively, in histone 3. Green arrow indicates induction of euchromatin conformation by SAGA-ADA complex. Truncated red line points to the suppression of euchromatin conformation by histone deacetylase enzymes (e.g., HdaA, HosA), and truncated green line points to the block of histone methylation carried out by LaeA. Heterochromatin and euchromatin are represented in red and green colors, respectively. Note that HosA is involved in deacetylation of H4 and H3.

histone methylation (Fig. 5). These data suggest that the expression of SM BGCs is under an epigenetic control by LaeA removing the heterochromatin marks, and by HepA binding and the consequent histone methylation to establish a heterochromatin structure. *hepA* encodes a putative heterochromatin protein, and its deletion leads to upregulation of SM biosynthetic genes, e.g., genes for aflatoxin, penicillin, terraquinone A biosynthesis in *Aspergillus* species (Reyes-Dominguez *et al.*, 2010).

Histone acetylation

The SAGA/ADA (Spt-Ada-Gcn5-acetyltransferase) complex was initially described as involved in regulation of fungal response to stress, e.g., oxidative stress and resistance to antimycotic compounds (Sellam *et al.*, 2009). This role is exerted through histone acetylation, which would have an opposite role to histone methylation in the regulation of the chromatin structural conformation (Fig. 5). GcnE/Gcn5p, a histone acetyl transferase should be the complex-subunit responsible for those acetylations, but this function should be carried out in interaction with Ada/Ada2p (Alteration/deficiency in activation), another component of the SAGA/ADA complex (Sellam *et al.*, 2009).

In *A. nidulans*, GcnE was shown to induce acetylation of histone 3 lysine 14 in orsellinic BGC, but interestingly only in interaction with *Streptomyces rapamycinicus* (Netzker *et al.*, 2015). Thus, this interaction induces the expression of the cryptic orsellinic acid BGC by promoting a change in the histone acetylation profile. Furthermore, acetylation of histone 3 in lysine 9 had a wider effect on the *A. nidulans* secondary metabolism, upregulating genes belonging both to the orsellinic acid and to the sterigmatocystin BGCs (Nützmänn *et al.*, 2011).

Histone deacetylases would be involved in the removal of acetyl groups from the amino-terminal tail of core histones (Tribus *et al.*, 2005). Thus, their function will enhance the heterochromatin conformation, and eventually will negatively affect the expression of SM BGCs. Several enzymes with this function have been characterized, e.g., HdaA (histone 3 deacetylase) and HosA (histone 3, histone 4 deacetylase). Furthermore, deletion of *hosA* gene in *A. nidulans* resulted in an induction of expression of BGC involved in orsellinic acid and derivatives, and also in cichorine and aspercryptin biosynthesis (Pidroni *et al.*, 2018).

Mycotoxins and Mycotoxigenic Fungi: Risk and Management. A Challenge for Future Global Food Safety and Security

Claudio Altomare, Antonio F Logrieco, and Antonia Gallo, National Research Council, Bari, Italy

© 2021 Elsevier Inc. All rights reserved.

Introduction

Molds are microscopic filamentous fungi, which cause food and feed spoilage. Moldy foods and feeds may pose a serious risk to the health of consumers due to fungal toxic metabolites produced in the course of spoilage, referred to as mycotoxins. Mycotoxins are by definition “fungal metabolites which when ingested, inhaled or absorbed through the skin cause lowered performance, sickness or death in man or domestic animals, including birds” (Pitt, 1996). By convention, the mushroom toxins and compounds that are toxic only to lower animals, such as invertebrates, are not regarded as mycotoxins. Toxigenic molds may act as plant parasites that colonize living plants in the field and/or may grow saprophytically on the products after harvest and throughout the entire production chain if environmental conditions, particularly temperature and moisture, are conducive to molding. Mycotoxins can be synthesized during either one or both of these invasive processes, as products of secondary metabolism of molds. Mycotoxins in food and feed may be fatal or cause severe illness at very small concentrations, often measured in parts per million (ppm) or parts per billion (ppb). Besides acute toxicoses due to high-dose mycotoxin exposure, the prolonged exposure to low and sub-lethal doses of mycotoxin results in chronic toxicosis, that is cumulative damages to specific tissues, organs or systems, sometimes associated to development of cancer (International Agency for Research on Cancer IARC, 2012a,b). Chemically, mycotoxins are structurally diverse compounds of low molecular weight that are synthesized from few precursors generated within the primary metabolism (Zeilinger *et al.*, 2015). The Food and Agriculture Organization (FAO) has estimated that 25% of the global food and feed output is contaminated by mycotoxins each year, with estimated losses of around 1 billion metric tons of foods and food products. Locally, these figures may increase, even considerably, in particular years when climatic conditions favorable to crop disease outbreak occur.

Contamination of foods and feeds with mycotoxins has been recognized as a matter of global concern since the early 1960s when a severe outbreak in poultry, the Turkey “X” disease, which killed 100,000 turkeys in the UK was discovered to be caused by consumption of moldy feedstuff contaminated with aflatoxin. However, the association between consumption of moldy grains and some human and animal diseases has been recognized since historical times (Pitt and Miller, 2017). Just to cite a few examples, the ergotism, a human disease resulting from the infection of rye by the fungus *Claviceps purpurea* is mentioned in the Old Testament and is recognized as an important cause of human mortality in Europe during the middle age. Also the trichothecenes, a group of mycotoxins produced by *Fusarium* species that infect wheat and other cereal grains, are thought to be linked to middle age plague epidemics. A human toxicosis (a pathology caused by exposure to a toxin) from consumption of *Fusarium*-infected grains occurred in southern Japan at the end of 1800; symptoms consisted in nausea, vomiting, diarrhea, abdominal pain, fever, and throat irritation. Similar toxicoses in humans, associated to the ingestion of moldy grains infected by *Fusarium* species, were also reported at the beginning of 1900 in China, Korea and Russia. The heart-attacking paralysis known as “acute cardiac beriberi”, was reported in Japan and in a number of other Asian areas from the 17th century on. Beriberi was correlated epidemiologically to the consumption of moldy rice contaminated with the *Penicillium* mycotoxin citreoviridin. More recently, serious human toxicoses occurred in Kenya in the years 2004, 2005 and 2006, with hundreds of affected people and almost 200 fatalities recorded as a consequence of aflatoxin poisoning from contaminated maize (Schmale and Munkvold, 2014a).

This chapter offers an overview on the main mycotoxins and the relevant producing molds, including their economic and health impact, epidemiology, biosynthesis and genetics, regulation and management. The methods for the analysis of mycotoxins are out the scope of this chapter; comprehensive reviews and up to date information on that topic can be found in Maragos and Busman (2010) and Tittlemier *et al.* (2019).

Social and Economic Impact of Mycotoxins

Aside from the obvious social implications for public health (see the toxic effects of individual mycotoxins, later on in this chapter), the occurrence of mycotoxigenic fungi and mycotoxins in food and feed chains has also major economic impacts to human society. These include (1) reduction of crop output due to plant diseases and from the removal of infected and/or damaged product (sorting), (2) reduced quality and commercial value of produce, (3) reduced animal productivity due to health problems associated with consumption of mycotoxin-contaminated feed, and (4) costs for humans and animals health care (Schmale and Munkvold, 2014b). The extra production expenses for the control of mycotoxigenic fungi outbreaks, such as the use of selected resistant cultivars and fungicides spraying or for the adoption of specific measures of prevention (e.g., biological control) have also to be taken into account. At post-harvest, the multiple control strategies that have been developed to mitigate the mycotoxin risks in the course of storage, transportation or processing and the cost for the organization and functioning of a surveillance network are all additional burdens for farmers, handlers, processors and, ultimately, for consumers.

Estimations of the costs of mycotoxins are not available for all the world regions. In the USA, the total cost has been estimated 0.5–1.5 billion USD per year; Council for Agricultural Science and Technology CAST (2003) reports a yearly cost of 0.9 billion for

crop losses of corn, wheat, and peanuts plus an additional 0.5 billion for regulatory enforcement, testing, and quality control measures. In developing countries, it is likely that losses exceed those in the USA. For instance, in three Asian countries (Indonesia, Philippines, and Thailand) annual losses were estimated at 0.9 billion USD for aflatoxins only (Schmale and Munkvold, 2014b).

Even if prevention measures are enforced, sometimes these are not effective enough to avoid the occurrence of mycotoxins at levels close or above the maximum allowable levels for food, resulting in low quality and reduced price of the produce or, in the worst scenarios, in rejection of lots or diversion towards alternative and low revenue uses, such as feed production or conversion to bioethanol. Many staple agricultural commodities such as wheat, rice, barley, corn, sorghum, soybeans, groundnuts and oilseeds are at high risk of mycotoxin contamination. For this reason, regulations on allowable levels of mycotoxins in staple food have been set and are strictly enforced by most countries. However, standards vary greatly among countries, particularly between developed and developing countries, and this difference may cause major trade issues in the globalized market. For some developing countries, where agricultural commodities account for a large part of the total national export, the economic impact of rejection of mycotoxin-contaminated products, as for both lost trade and additional costs for inspection, disposal and compensation in the case of claims, is considerable (Gbashi *et al.*, 2019; Taniwaki *et al.*, 2019). Also, the stricter mycotoxin standards for imported products applied in the developed countries may prompt the developing countries to export their best quality foods and keep the more heavily contaminated foods for domestic consumption, resulting in higher exposure of people to mycotoxins in those countries. This situation raises ethical and social issues and highlights the need for a more effective international cooperation on the fronts of standards harmonization and scientific research (Logrieco *et al.*, 2018). The climatic conditions in developing countries of the tropical zone favor proliferation of mycotoxigenic fungi and the accumulation of mycotoxins. Mycotoxin mitigation measures are costly and the control strategies should be implemented at multiple points of the production chain, through an organized and coordinated infrastructural system of control, surveillance and communication, which in some developing countries may be difficult to set (International Agency for Research on Cancer IARC, 2012b). To successfully implement such a system it is important that the expected benefits, in terms of trade and health, exceed their costs. In this sense, the role of scientific research for the development of effective low-cost mitigation strategies is of utmost importance.

While the human health losses from adverse effects of mycotoxins are primarily relevant to the social impact of mycotoxins, they have also economic impacts that can be evaluated by the tools of health economics. This cost can be calculated in two ways. The first is cost of illness, which is mainly relevant to developed countries because a large portion of the cost is health-care related. The second is disability-adjusted life years, which is applicable to both developed and developing countries (International Agency for Research on Cancer IARC, 2012b). Vardon *et al.* (2003) estimated the total losses due to the three main mycotoxins, aflatoxin, fumonisin and deoxynivalenol, in the USA to be as high as 1 billion USD per year; this cost was largely due to market losses, because human health effects are almost negligible in countries where a strict regulation and an effective surveillance are enforced. On the contrary, in the developing countries the loss should be calculated as a combination of market impacts, mainly due to rejection of contaminated lots, and adverse health effects on local consumers (Gbashi *et al.*, 2019).

Regulated Mycotoxins and Associated Fungi

Virtually all the plant pathogenic fungi are able to produce, in appropriate conditions, secondary metabolites that are toxic to invertebrate or vertebrate animals. To date, approximately 400 toxic secondary metabolites of fungal plant pathogens have been discovered. Many of these have been isolated from laboratory cultures and only a relatively limited number of them have been found to occur under natural conditions, where they play the roles of chemical weapons against competing microorganisms and grazing animals, of virulence factors, or of signaling molecules within ecological interactions. Among the naturally occurring fungal toxins only few are considered mycotoxins of significance for human and animal health because of their high toxicity, levels produced (especially in certain epidemiological conditions), or chances of exposure and intake. The most important mycotoxigenic fungal species belong to the genera *Aspergillus*, *Penicillium* and *Fusarium*, which can contaminate staple crops and widely consumed foods (Table 1), such as cereals (maize, wheat, barley, oats and rice), nuts, oilseeds, fruits, dried fruits, vegetables, cocoa and coffee beans, wine, beer, herbs, and spices and therefore pose a risk to a large number of people and animals (See "Relevant Website section"). To protect consumers from health risks, many countries have adopted regulations to limit exposure to the major mycotoxins. A study from 2003 by the United Nations' Food and Agriculture Organization (FAO) on worldwide regulations for mycotoxins reported that at that time approximately 100 countries had established guidance and regulations on mycotoxin in food and feed (FAO, 2004). To date, the figures are possibly higher, but still there are countries, including a number of African countries, which do not have specific regulation for food safety (Matumba *et al.*, 2015). Also, many countries have regulated the tolerable levels for at least aflatoxin B₁ (AFB₁) or the sum of aflatoxins B₁, B₂, G₁ and G₂ in human food, but relatively few countries have established strict limits for other mycotoxins such as fumonisin (FUM), ochratoxin A (OTA), and deoxynivalenol (DON). For, instance, in the USA, maximum tolerated levels have been set by the Food and Drug Administration (FDA) for aflatoxins in food and feed and for patulin, but only guidance levels are given for DON and FUM in food and feed (FDA, 2000).

The various regulations set the limits for the content of mycotoxins in food and feed and, naturally, they have profound implications for health safety as well as for economic interests of producers and traders. However, the different perceptions of tolerable health risks of mycotoxins at global level, mainly associated to the level of development and susceptibility of crops to contamination in different countries, has led to lack of consensus about standards for regulated mycotoxins in food and feed (Tables 2 and 3). For example, of the 48 countries which in 2003 had established limits for total aflatoxins in food, standards ranged

Table 1 Major mycotoxins and mycotoxigenic fungi

<i>Mycotoxin</i>	<i>Main producing mold (s)</i>	<i>Commodities</i>	<i>Animals affected</i>	<i>Toxic effect (s)</i>
Aflatoxins (B ₁ , B ₂ , G ₁ , G ₂ , M ₁ , M ₂)	<i>Aspergillus flavus</i> , <i>A. parasiticus</i>	Corn, peanuts, cottonseed, pistachios, figs, tree nuts, wheat, rice, spices, copra, dairy products	Humans, cattle, sheep, swine, aviary species, dogs, cats	Liver tumors in humans (IARC, Group 1), hepatotoxicity, bile duct hyperplasia, hemorrhage of the intestinal tract and kidneys, teratogenicity, immune suppressive
Ergot alkaloids	<i>Claviceps purpurea</i> , <i>C. africana</i> , <i>C. sorghi</i>	Rye, sorghum, cereals, pasture grasses	Cattle, sheep, horses, humans (rare)	Hallucinations, gangrene, lameness, agalactia, reduced weight gain, abortion
Fumonisin B ₁	<i>Fusarium verticillioides</i> , <i>F. proliferatum</i>	Corn, corn silage	Humans, horses, swine	Esophageal cancer in humans (IARC Group 2B), carcinogenic, neural tube defects, liver damage, heart failure, encephalomalacia (horses), pulmonary edema (swine),
Ochratoxin A	<i>Aspergillus carbonarius</i> , <i>A. niger</i> , <i>A. ochraceus</i>	Grapes, raisins, wine, coffee, tree nuts, figs	Humans, swine, poultry	Kidney dysfunction (nephropatia), tumors in urinary tract (IARC, Group 2B)
Patulin	<i>Penicillium verrucosum</i> , <i>P. nordicum</i> <i>Penicillium expansum</i> , <i>P. crustosum</i> , <i>P. urticae</i> , <i>P. griseofulvum</i> ; <i>Aspergillus clavatus</i> , <i>A. terreus</i>	cereal grains, spices, cheese, meat Apples, plums, grapes, peaches, pears, apricots, fruit juices	Humans	Nephropathy, feed refusal Carcinogenic in laboratory animals, damage in the brain, liver and kidneys of experimental animals, neurotoxic, immunotoxic, genotoxic and teratogenic effects of chronic exposure
Trichothecenes	Type B (deoxynivalenol, nivalenol, fusarenon-X): <i>Fusarium graminearum</i> , <i>F. cerealis/crookwellense</i> , <i>F. culmorum</i>	Wheat, barley, oats, corn	Swine, dairy cattle, poultry, horses, humans	feed refusal in swine, reduced weight gain and vomiting; gastrointestinal problems, diarrhea
	Type A (T-2 toxin, HT-2 toxin, neosolaniol, 4,15-diacetoxyscirpenol): <i>F. sporotrichioides</i> , <i>F. langsethii</i> , <i>F. sambucinum</i> , <i>F. equiseti</i>		Humans	nausea, fever, headaches, vomiting, leucopenia (aleukia), hemorrhaging and degeneration of bone marrow, skin inflammation
Zearalenone, Zearalenols	<i>F. graminearum</i> , <i>F. culmorum</i> , <i>F. equiseti</i> , <i>F. cerealis/crookwellense</i>	Corn, wheat, hay	Swine, cattle	Vulvovaginitis, vaginal prolapse, rectal prolapse, anestrus and fertility problems, abortion, malformation of testicles and ovaries

Table 2 Standards for mycotoxins in food adopted in some countries and recommended by the Codex Alimentarius

Country/Regulation ^a	Food	Max. Levels ($\mu\text{g/Kg}$ = ppb, unless otherwise specified)
AFLATOXINS (sum of $B_1 + B_2 + G_1 + G_2$)		
Brazil	Cereals and cereal-based food except maize, beans, cocoa and cocoa products	5
	Maize and maize products	20
	Spices	20
	Chestnuts, hazelnuts, almonds, pistachios, dried fruits	10
	Brazil nuts	15 in nuts for further processing 10 in nuts for direct consumption
China	Wheat, barley, other grains, beans, nuts and seeds	5
	Rice and rice oil	10
	Corn and peanuts	20
	Formulated food for infants	0.5
Codex	Peanut, almond, hazelnut, pistachios, dried figs	15 in nuts for further processing 10 in nuts for direct consumption and dried figs
European Union (EU)	Groundnuts, oilseeds	8 (AfB ₁) and 15 (total) in products for further processing 2 (AfB ₁) and 4 (total) in products for direct consumption
	Hazelnuts, brazil nuts	8 (AfB ₁) and 15 (total) in products for further processing 5 (AfB ₁) and 10 (total) in products for direct consumption
	Almond, pistachios, apricot kernels	12 (AfB ₁) and 15 (total) in products for further processing 8 (AfB ₁) and 10 (total) in products for direct consumption
	Dried fruits other than figs, other tree nuts	5 (AfB ₁) and 10 (total) in products for further processing 2 (AfB ₁) and 4 (total) in products for direct consumption
	Cereals and cereal-based products	2 (AfB ₁) and 4 (total)
	Processed cereal-based foods and baby foods for infants and young children	0.1 (AfB ₁)
United States Of America (USA)	All foods except milk	20
AFLATOXIN M₁		
Brazil	Liquid milk - cheese - powdered milk	0.5–2.5 - 5
China	Liquid milk and dairy products, powdered milk for infants	0.5
Codex	Liquid milk	0.5 (a concentration factor applies to partially or wholly dehydrated milks)
EU	Milk - milk for infants	0.05–0.025
USA	Milk, milk products	0.5
ERGOT ALKALOIDS		
EU	Unprocessed cereals with the exception of corn and rice	0.5 g of ergot sclerotia/Kg
FUMONISINS B₁, B₂, B₃		
Brazil	Maize flour and maize meal - raw maize	2000–4000
USA	Maize and maize products, sorghum, asparagus	2000–4000
Codex	Raw maize	4000 ($B_1 + B_2$)
	Maize flour, maize meal	2000 ($B_1 + B_2$)
EC	Unprocessed maize	4000
	Maize intended for direct human consumption	1000
	Maize-based breakfast cereals and maize-based snacks	800
	Processed maize-based foods and baby foods for infants and young children	200

(Continued)

Table 2 Continued

Country/Regulation ^a	Food	Max. Levels ($\mu\text{g/Kg}$ = ppb, unless otherwise specified)
OCHRATOXIN A		
China	Roasted and ground coffee, roasted coffee beans, beans, cereals and ground cereal products	5
	Grape wine	2
Codex	Raw wheat, barley and rye	5
EC	Cereals and cereal-derived products for adults	3 (unprocessed) – 5 (processed)
	Roasted coffee beans and ground roasted coffee, excluding soluble coffee	5
	Wine, aromatized wine, grape juice	2
	Processed cereal-based foods and baby foods for infants and young children	0.50
USA		Not set
PATULIN		
China	Fruits and fruit products (except haw rolls), fruit and vegetable juices/beverages, cider and haw wine	50
Codex	Apple juice	50
USA	Apples, apple juice and concentrate	50
EC	Fruit juices, concentrated fruit juices, spirit drinks, cider and other fermented drinks derived from apples	50
	Solid apple products	25
	Apple juice and apple puree for infants and young children, baby food	10
TRICHOTHECENES		
DEOXYNIVALENOL (DON)		
China	Corn and corn products, barley, wheat and wheat products	1000
Codex	Cereal grains for further processing	2000
	Flour, semolina and flakes derived from wheat, maize or barley	1000
	Cereal based food for infants and young children	200
EC	Unprocessed cereals and maize	1750 (durum wheat, oats and maize) – 1250 (other cereals)
	Cereals intended for direct human consumption, pasta	750
	Processed cereal-based foods and baby foods for infants and young children	200
USA	Cereals, cereal products	1000
ZEARELENONE (ZEA)		
China	wheat and wheat flour, corn and corn products (flour, flakes and grits)	50
EC	Unprocessed cereals and maize	100 (cereals other than maize) – 350 (maize)
	Cereals, cereal flour, bran and germ intended for direct human consumption	75
USA		Not set

Table 3 Standards for mycotoxins in feed adopted in some countries

Country/Regulation	Feed	Max. Levels (mg/Kg = ppm)
AFLATOXIN B₁		
China ^a	Corn-derived feed ingredients; Feed products	0.01–0.05
Codex ^b		Not set
European Union (EU) ^c	Feed materials, except compound feed for dairy and young animals	0.02 (relative to a feed with a moisture content of 12%)
	Complementary and complete feed	0.01 (relative to a feed with a moisture content of 12%)
	Compound feed for dairy cattle and calves, dairy sheep and lambs, dairy goats and kids, piglets and young poultry animals	0.005 (relative to a feed with a moisture content of 12%)
United States of America (USA) ^d	Corn and peanut products intended for breeding or finishing: Cottonseed meal intended for beef cattle, swine, or poultry	0.2–0.3
	Corn, corn products, peanut products, cottonseed meal, and other animal feeds and feed ingredients for immature and dairy animals	0.02
ERGOT SCLEROTIA		
EU	Feed materials and compound feed containing unground cereals	1000 (relative to a feed with a moisture content of 12%)
FUMONISINS B₁ + B₂		
China	Corn and corn products, corn silage and stover; concentrate supplements for ruminants; concentrated and compound feeds for poultry	20–60
	Concentrate supplements for horse and rabbit, concentrated feeds for swine, compound feeds for swine, rabbit, and horse	5
EU	Maize and maize-derived feed materials	60 (relative to a feed with a moisture content of 12%)
	Complementary and complete feedingstuffs	5–50 (relative to a feed with a moisture content of 12%)
USA	Corn and corn by-products intended for equids, swine, breeding ruminants, breeding poultry and breeding mink (includes lactating dairy cattle and hens laying eggs for human consumption)	5–30
	Poultry; All other species or classes of livestock and pet animals	10–100
OCHRATOXIN A (OTA)		
China	Grains and grain products; compound feeds	0.1
EU	Feed materials (cereals and cereal products)	0.25 (relative to a feed with a moisture content of 12%)
	Complementary and complete feedingstuffs	0.05 – 0.1 (relative to a feed with a moisture content of 12%)
TRICHOTHECENES		
DEOXYNIVALENOL (DON)		
China	Plant feed ingredients	5
	Compound feeds; concentrate supplements	1–3
EU	Feed materials	8–12 (relative to a feed with a moisture content of 12%)
	Complementary and complete feedingstuffs	0.9 – 5 (relative to a feed with a moisture content of 12%)
USA	Grains and grain by-products	10 (ruminating beef and chickens), 5 (swine and other animals)

(Continued)

Table 3 Continued

Country/Regulation	Feed	Max. Levels (mg/Kg = ppm)
<i>T-2 TOXIN (T-2)</i>		
<i>China</i>	Plant feed ingredients; Formula feeds for swine and poultry	0.5
<i>SUM T-2 + HT-2 TOXIN</i>		
<i>EU^d</i>	Cereal products for feed and compound feed	0.25–2 (relative to a feed with a moisture content of 12%)
<i>ZEARELENONE (ZEA)</i>		
<i>China</i>	Feed ingredients	0.5–1.5
	Formula feeds for young sow, piglet, swine; Concentrate supplements for calf, lamb, and animals in lactation	0.1–0.5
<i>EU</i>	Feed materials	2–3 (relative to a feed with a moisture content of 12%)
	Complementary and complete feedingstuffs	0.1– 0.5 (relative to a feed with a moisture content of 12%)

from 0 to 50 µg/Kg (ppb) (Dohlmán, 2003). Most of the limits are set for human foods. Typically, higher regulatory levels are used for animal feed.

One more complication may arise from some countries that under the “precautionary principle” may want to set standards on certain mycotoxins for which scientific evidence of a health risk is not yet well-established. In this respect, harmonization of regulations and guidelines for production and surveillance is a crucial issue, with the aim to find an acceptable balance between health benefits and economic and trade costs. For this reason, a joint scientific expert committee (Joint FAO/WHO Expert Committee on Food Additives, JECFA) of the FAO and the World Health Organization (WHO), has been instituted as the international body responsible for evaluating the health risk from mycotoxins. International standards and codes of practice to limit exposure to mycotoxins from certain foods have been established by the Codex Alimentarius Commission based on JECFA assessments (Codex Alimentarius, 2015). However Codex standards are advisory, not mandatory, and the national standards may divert significantly from the Codex recommendations.

Aflatoxins

Aflatoxins (Afls) are the most important mycotoxins worldwide, for toxicity, occurrence and economic impact. Different forms of Afls exist and the main types are aflatoxin B₁ (AflB₁) which is the major toxin produced, B₂ (AflB₂), G₁ (AflG₁), and G₂ (AflG₂); farm animals metabolize these forms and transform them in the less harmful aflatoxins M₁ (AflM₁) and M₂ (AflM₂), which are found in milk, meat and other dairy products. Afls are produced primarily by the fungi *Aspergillus flavus* (AflB₁ and AflB₂) and *A. parasiticus* (AflB₁, AflB₂, AflG₁ and AflG₂). Other *Aspergillus* species, viz. *A. nomius*, *A. sergii*, *A. bombycis*, *A. minisclerotigenes*, *A. parvisclerotigenes*, *A. pseudocaelatus*, *A. pseudotamari*, and *A. ochraceoroseus* also are aflatoxigenic (Varga *et al.*, 2011), but their significance for mycotoxin occurrence is negligible. Generally regarded as saprophytes, *Aspergillus* spp. grow on a large number of substrates. Under favorable conditions, some species exhibit limited parasitic abilities and can colonize crops in the field. *Aspergillus flavus* and *A. parasiticus* are xerophyte species that can grow well and proliferate in environments with low water activity ($a_w \leq 0.85$) and under drought condition.

Afl contamination occurs in major crops such as maize, peanuts, cottonseed, pistachios, figs, tree nuts, cereal grains and spices, and derived foods and feeds (Council for Agricultural Science and Technology CAST, 2003). In maize, *A. flavus* develops on the surface of the ears, with the infected parts that become covered with masses of gray-green spores. Afls may be produced by the fungus in the field until the kernel reaches about 15% of moisture. Cottonseed, may become contaminated with Afls if the seed-bearing capsules are damaged in conjunction with high humidity and warm temperatures before or after harvest. Tree nuts such as pistachios and almonds may also be infected following injuries, such as the splitting of hulls. In peanut *A. flavus* and *A. parasiticus* cause a disease known as yellow mold, and high levels of Afl contamination may result following relatively high temperatures and moderate humidity. Infection of crops by aflatoxigenic species and production of Afls in the field are affected by various factors including environmental conditions (hot and humid weather), drought plant stress in conjunction with high temperatures, mechanical injuries caused by plant grazing insects, and plant genotype (Diener *et al.*, 1987; Council for Agricultural Science and Technology CAST, 2003). Williams *et al.* (2004) defined the sub tropical and warm temperate regions located at latitudes between 40°N and 40°S as the “hot zones” for Afl risk, and estimated that 4.5 billion people living in those areas are chronically exposed to Afls. It is expected that in the future temperate regions will become more subjected to Afl outbreaks, because of global Earth warming. Afls often occur together with cyclopiazonic acid, another *A. flavus* mycotoxin, in groundnuts and with cyclopiazonic acid and the *Fusarium* toxins fumonisins in maize.

Usually, field contamination increase during postharvest activities, e.g., crop drying, or in storage if conditions, particularly moisture, are favorable to molding. However, in some cases, molding and Afls contamination can occur even in the absence of previous field infection, if the commodity is stored improperly. Afls are temperature-stable compounds and can resist to heat treatments used for food and feed processing, such as ultrahigh-temperature (UHT) treatment, pasteurization, roasting, and baking, and also to cold storage.

The Afls are potent liver toxins and most animal species exposed to Afls show signs of liver disease, ranging from acute to chronic. AflB₁ is a potent hepatocarcinogen and is classified as a Group 1 compound (carcinogenic to humans) by the International Agency for Research on Cancer (International Agency for Research on Cancer IARC, 2012a). AflB₁ is also an immune suppressor and cause malnutrition and growth impairment in both humans and animals (Rushing and Selim, 2019). The kidney can also be affected in pigs and goats.

Afls have been linked to cases of acute poisoning and chronic aflatoxicosis in humans and animals (Pitt *et al.*, 2012). In humans, Afls have caused outbreaks of acute hepatitis. The association of ingestion of Afl-contaminated grains with inflammation of the liver is well supported by epidemiological evidences, most notably by the observations of outbreaks of acute hepatitis associated with consumption of maize heavily contaminated with aflatoxin in Kenya in 1981 and 2004, which resulted in several hundred deaths. Previously, sporadic cases of aflatoxicosis were reported in Western India (1974) and Malaysia (1988). The intake of total Afls estimated to result in a risk of fatality was >1 mg/day, i.e., >20 µg/kg body weight (bw)/ day in adults, while aflatoxicosis without fatality may occur with 5–10-fold lower doses (Wild and Gong, 2010). Among the livestock, the most sensitive animals for acute toxicity are the avian species, primarily ducklings, followed by turkeys, chicks and quail. In other farm animals, decreasing level of sensitivity is shown by rabbits, young pigs, calves, mature cattle and sheep (Pitt *et al.*, 2012). Dogs are also quite sensitive to acute toxicity. The susceptibility of a species to toxicity of Afls depends on its ability to metabolize the toxin efficiently and quickly to less toxic or nontoxic metabolites. Undernourished or stressed animals are more sensitive to Afls.

Ergot Alkaloids

The ergot alkaloids (EAs) are mycotoxins produced by several species in the genus *Claviceps*, pathogens of cereals and grasses. There are four main groups of EAs, viz., the clavines, the lysergic acids, the lysergic acid amides, and the ergopeptides. The most important compound is ergotamine that belongs to the group of ergopeptides and is precursor of the psychoactive drug lysergic acid diethylamide (LSD). EAs accumulate in specialized resting structures (sclerotia) formed by the fungus in plant heads and spikes which are infected during cool, wet weather. Infection of flowers of susceptible hosts by *Claviceps* spp. results in replacement of the ovary by a sclerotium made of a hard and dense mass of fungal hyphae, trivially called, as well as the disease itself, “ergot” (Alderman *et al.*, 1999). The name *ergot* means ‘spur’ in French, since grains colonized with *Claviceps* spp. often resemble the spurs on the legs of a rooster. The sclerotia are usually white, black, or tan and are 1–4 times as large as the seeds they replace. The most important species is *C. purpurea*, which forms dark purple to black sclerotia. *Claviceps purpurea* is distributed worldwide in temperate climates and has a host range of more than 200 grass species. It is most prevalent on rye, but also occurs on barley, oats, and wheat, as well as wild and cultivated grasses, but not on sorghum or maize. *Claviceps africana*, also of importance in terms of mycotoxins, is a cause of a serious disease resulting in malesterile sorghum seed.

Ergots may be harvested with the grain and processed into flour or used for feed, resulting in high levels of contamination with EAs and in human and animal mycotoxicosis known as ergotism. EAs have biological properties of neurotransmitters and are vasoconstrictors; thus ergotism may have two different forms, that is gangrenous, affecting blood supply to extremities, and convulsive, affecting the central nervous system. Clinical symptoms are hallucinations, the feeling of itchy and burning skin, gangrene, loss of hands and feet, and even death. The biological activity of the sclerotia of *Claviceps* spp. was known in China more than 5000 years ago and ergotism is one of the oldest known human diseases caused by mycotoxins. The historical disease from the Middle Ages called St. Anthony’s Fire, characterized by symptoms such as intense inflammation of the skin, sensation of insects crawling under their skin, gangrene and loss of hands and feet is thought to be the outcome of ergot poisoning. Also, EAs might have been the cause of hallucinations associated with witchcraft collective hysteria in the surrounding of Salem, Massachusetts, in the 1690s. It has been speculated that ergotism may have killed hundreds of thousands of people in Europe during the last millennium (Smith and Moss, 1985). Modern methods of grain sorting have significantly reduced the occurrence of ergotism as a human disease, but EAs are still an important issue in respect to contamination of feeds and mycotoxicosis in livestock. In the last century, cases of ergotism were reported in pigs, cattle sheep and horses consuming sorghum-based feeds or feeds based on small grains, such as rye and barley, or foraging on infected grasses contaminated (Council for Agricultural Science and Technology CAST, 2003; Cross, 2003). The symptoms include lameness, gangrene of the extremities (feet, ears, and tail), reduced milk production (agalactia), reduced weight gain, abortion, hypersensitivity, ataxia, convulsions, and, in sheep, intestinal inflammation. According to the European Food Safety Authority EFSA (2012) opinion, there is no evidence that EAs are transferred from animal feed to animal products, such as milk and meat and therefore these are unlikely to be an important source of human exposure to EAs. The EU has not set standard for EAs, but adopted a limit of 0.5 g/Kg of ergot sclerotia for oats, wheat, durum wheat and other unprocessed cereal grains except maize and rice, intended for human consumption (Table 2). However, the content of ergot sclerotia not always correlates well with the content in EAs, since it is possible high levels of EAs occur in grain with very little visible sclerotia, due to their fragmentation during harvesting and processing. Rye ergot in feed materials and compound feed containing unground cereals is also restricted to a maximum content of 1000 mg/kg relative to moisture content of 12%. Few countries besides the EU have standards for EAs or ergot sclerotia. Australia and New Zealand set a limit of 0.5 g/kg of ergot sclerotia in cereal grains. In Canada, guidelines for ergot sclerotia in cereals establish a quality grading, ranging from 0.01% for the highest quality, to 0.1% for the lowest quality. Also, maximum levels of EAs have been established for pig feed (6 mg/kg), feed for cattle, sheep and horses (3 mg/kg) and feed for chicks (9 mg/kg).

Fumonisin

The fumonisins (FUMs) are a group of mycotoxins produced mainly by *Fusarium verticillioides* and *F. proliferatum* and by a few other *Fusarium* species of minor importance (Pitt *et al.*, 2012). The species name *F. moniliforme*, often associated to production of FUMs in the earliest reports, is no longer in use. Fumonisin B₂ and B₄ are produced also by the species *Aspergillus niger* (Frisvad *et al.*, 2007; Mogensen *et al.*, 2010). Recent information indicates that FUM production by *A. niger* is rather common. Since *A. niger* is common in some fresh fruits, particularly berries, and on onions, FUMs produced by *A. niger* can be expected to be more widespread than currently assumed (Pitt *et al.*, 2012). To date, 28 types of FUM have been identified, which are classified into four groups: FUMs A, B, C, and P. Fumonisin B₁ (FB₁) is the most common and economically important form, followed by fumonisins B₂ and B₃ (Escrivá *et al.*, 2015). *Fusarium verticillioides* and *F. proliferatum* are ubiquitous species and the most common fungi associated with maize, where they cause the “Fusarium ear rot”. *Fusarium verticillioides* has an endophytic nature; it can infect maize plants systemically without causing visible disease symptoms, and is found in symptomless systemically-infected seeds. FUMs can be found in a few other crops, typically at low levels, but their economic importance is mainly in maize. Epidemiological studies have clearly demonstrated the importance of drought stress, insect damage, hybrid genotype and, most importantly, temperature for FUM occurrence. Contamination of maize and maize-based products destined for human and animal consumption with FUMs are most likely to occur in the tropical, subtropical and warm areas of the world and in temperate growing regions, including those in North America and Europe. FUMs are often co-produced together with other toxins, such as fusaric acid, fusarins and moniliformin (Desjardins and Proctor, 2001). The International Agency for Research on Cancer (IARC) identified FB₁ as possibly

carcinogenic to humans (group 2B) and it has been proven to be carcinogenic to laboratory animals. Some studies indicate that FB₁ causes an increased prevalence of esophageal cancer in humans and toxic effects against nervous and cardiovascular systems, liver, lung and kidney in animals (Stockmann-Juvala and Savolainen, 2008). FUMs were characterized in the late 1980s, as a result of studies into the causes of esophageal cancer in Africa, coupled with outbreaks of equine leukoencephalomalacia and porcine pulmonary edema in the U.S., both associated with the consumption of corn-based feeds. Leukoencephalomalacia is a fatal disease of horses with symptoms that include drowsiness, blindness, staggering, and liquefaction of brain tissue. In swine, symptoms of FUM poisoning are reduced feed intake and weight gain, liver damage; poisoned pigs can develop a fatal disease known as pulmonary edema, i.e., fluid accumulation in the tissue and air spaces of the lungs.

Ochratoxin A

Ochratoxins are mycotoxins produced by several species of *Aspergillus* and *Penicillium* (Wang *et al.*, 2016). There are three types of ochratoxins, namely A, B, and C. Particularly, ochratoxin A (OTA) is the most common and important one for public and animal health; ochratoxins B and C are less toxic and less common. OTA was originally described as a metabolite of *Aspergillus ochraceus* and subsequently isolated from a number of different *Aspergillus* species. However, the first report of natural occurrence of OTA was from a *Penicillium viridicatum* strain, later re-identified as *P. verrucosum*. The most important producers of OTA are the “black aspergilli” (*Aspergillus* Section *Nigri*) *A. carbonarius* and *A. niger*, which are commonly found in grapes, dried vine fruits, wine, and coffee. *Aspergillus ochraceus* and related species, which produce this toxin in coffee and sometimes in stored grains are less common producers. The only *Penicillium* species that produce OTA are *P. verrucosum*, and the closely related *P. nordicum*. *Penicillium verrucosum* commonly occurs in cereals in cool temperate climates, whereas *P. nordicum* has been isolated, uncommonly, from processed meats.

Contamination of commodities with OTA generally occurs because of poor storage conditions or non-optimal drying practices. OTA is a chemically stable compound; hence, ordinary food processing do not reduce its presence in foods and beverages significantly (Malir *et al.*, 2016). OTA has proven to induce kidney and liver tumors in laboratory animals and is classified by IARC as a Group 2B compound (possible human carcinogen) (International Agency for Research on Cancer IARC, 1993). OTA is mainly a nephrotoxin and is thought to be the cause of a chronic kidney disease in humans known as Balkan endemic nephropathy that occurred in the early 1970s. Recent studies have provided a link between ochratoxin exposure and human testicular cancer in Europe and tumors in the human urinary tract. Cases of ochratoxicoses of farm animals have been reported in pigs and poultry, with main clinical signs being renal dysfunction (nephropathy), edema and feed refusal. In pigs, excessive thirst (polydipsia) and passage of large volumes of urine (polyuria) are characteristic signs of this disease. Ochratoxins assumed with feed are transferred to blood, milk and muscle tissue of animals (Bui-Klimke and Wu, 2015) and thus may be found in animal-derived-products (meat, milk and eggs). According to the European Food Safety Agency (EFSA, 2006), the estimated source of OTA exposure in adults in Europe is: 44% cereals, 10% wine, 9% coffee, 7% beer, 5% cacao, 4% dried fruits, 3% meat, 3% spices, and 15% others foods.

Patulin

Patulin (PAT) is a toxin produced primarily by *Penicillium expansum*, and secondarily by numerous other *Penicillium* and *Aspergillus* species that affect fruits. Compared to other mycotoxins PAT is regarded as less risky, because the production of significant levels of PAT is accompanied by visible rotting of the fruit, so nearly all the toxin can be removed by rejection of rotting fruits through selection and sorting. Nevertheless, concentrations of patulin in foods are subject to regulatory control in some countries. PAT-producing fungi have been isolated from various moldy fruits and vegetables. PAT has been reported primarily in apple and apple-based foods, and occasionally in other fruits, such as pears, plums, peaches, figs, oranges and grapes. Toxicological studies on PAT have shown that effects of ingestion include convulsions, agitation, ulceration, edema, intestinal inflammation, vomiting and DNA damage in the brain, liver and kidneys of experimental animals. Chronic exposure have also neurotoxic, immunotoxic, genotoxic and teratogenic effects. However, based on the lack of evidences in humans, IARC has classified PAT in Group 3 as not carcinogenic to humans (International Agency for Research on Cancer IARC, 1986). PAT is destroyed by the fermentation process and therefore it is not found in fermented apple beverages, such as cider, and its occurrence concerns primarily juices, which are produced with less strictly selected fruits. The European Community sets the limits to the concentrations of PAT in food products at 50 µg/kg in all fruit juices, fruit concentrates and fermented drinks derived from apples or containing apple juice, at 25 µg/kg in solid apple products used for direct consumption, and at 10 µg/kg in apple juice and solid apple products for infants and young children (European Commission (EC), 2006).

Trichothecenes

Trichothecenes are a large class of fungal sesquiterpenoid secondary metabolites produced by several species of *Fusarium*, *Myrothecium*, *Spicellum*, *Stachybotrys*, *Cephalosporium*, *Trichoderma*, and *Trichothecium* (Cole *et al.*, 2003). More than 200 trichothecenes are known to date, but only few of them have economic and safety importance because may contaminate staple products and cause myotoxicoses in humans and farm animals, all of them produced by *Fusarium* spp. Trichothecenes are classified into four

types (A–D), based on substitutions on the 12,13-epoxytrichothec-9-ene core structure (McCormick *et al.*, 2011). *Fusarium* species produce either type A or type B trichothecenes in cereals (Foroud and Eudes, 2009). The type B trichothecenes, characterized by a C-8 keto group, are produced mainly by *F. graminearum* and *F. culmorum*, and include the important trichothecenes deoxynivalenol (DON, a.k.a. vomitoxin because of its deleterious effects on the digestive system of monogastric animals), nivalenol (NIV), 4-acetylnivalenol (a.k.a. fusarenon-X, FUS-X) and acetylated derivatives thereof. Of these, by far the most common contaminant of food and feed is DON, but it has been reported that in Japan NIV is as prevalent as DON in wheat and barley (Nagashima, 2015). Type A trichothecenes include compounds that have at C-8 a hydroxyl group, an ester functional group, or no oxygen substitution. Type A trichothecenes are produced mainly by the species *F. sporotrichioides* and *F. langsethiae* and include the mycotoxins neosolaniol (NEOS), T-2 toxin (T-2), HT-2 toxin (HT-2) and 4,15-diacetoxyscirpenol (DAS). Trichothecene contamination is economically important in wheat, barley, oats, maize and triticale. In temperate climate regions there is a prevalence of *F. graminearum* and, less frequently *F. culmorum*, *F. crookwellense* and *F. avenaceum*. *Fusarium graminearum* (sexual stage *Gibberella zeae*) causes a disease of wheat and other small grains known as Fusarium head blight (FHB) and on maize a disease known as Gibberella ear rot (GER). In wheat, infected spikes exhibit premature bleaching as the pathogen progresses within the head, while on maize the ears infected with *F. graminearum* appear covered with a pinkish fungal mycelium. The infected grains and corn become contaminated with DON and other type B trichothecenes, and often also with the estrogenic mycotoxin zearalenone, produced by the same *Fusarium* species. Under cooler conditions, the type A trichothecene-producing species *F. sporotrichioides*, *F. langsethii*, and *F. equiseti* predominate. However, the regional and annual relative abundance of the above *Fusarium* species and the associated mycotoxins may vary, mostly affected by temperature.

The mechanism of toxicity of trichothecenes to eukaryotic cells is based on the inhibition of protein synthesis by interfering with initiation, elongation, and termination stages of the process; the mycotoxin affects peptidyl transferase enzyme binding the 60S ribosomal subunit, thus causing the inhibition of protein translation. In general, the trichothecenes are more cytotoxic than other *Fusarium* metabolites and the type A trichothecenes have a higher cytotoxic effect than type B trichothecenes. However, trichothecenes are not carcinogenic to humans, according to IARC evaluation (International Agency for Research on Cancer IARC, 1993). Most trichothecene toxicology studies have focused primarily on T-2 and DON (Pestka, 2010; Li *et al.*, 2011). In animals, trichothecenes aberrantly activate proinflammatory gene expression, disrupt gastrointestinal function and interfere with growth hormone action. Acute exposures to high trichothecene dosages in experimental animals induce anorexia, diarrhea, and vomiting; at extremely high doses, even more severe effects have been observed, including gastrointestinal hemorrhage, leukocytosis, circulatory shock, reduced cardiac output, and ultimately death. Chronic exposure of animals to moderate doses of trichothecenes induces food refusal and weight loss, impairment of the immune system function, and developmental diseases.

Trichothecenes are among the most important mycotoxin as for economic impact and food and feed safety. The IPCS/WHO reported that trichothecenes are cause of fatal and chronic intoxications on human and livestock (International Program on Chemical Safety IPCS & World Health Organization WHO, 1990). Human disease outbreaks associated with the consumption of DON-contaminated cereal grains and flour were reported in China and India. The symptoms included nausea, fever, headaches, and vomiting. In the 1940s in Russia, T-2 caused a fatal disease of humans known as alimentary toxic aleukia (ATA). Symptoms of ATA in humans included nausea, vomiting, diarrhea, leucopenia (aleukia), hemorrhaging and degeneration of bone marrow, skin inflammation, and sometimes death. In the 1970s–1990s, T-2 was used in Southeast Asia as a chemical warfare agent released by plane-spray and hence called “yellow rain”. As for livestock, trichothecenes, particularly DON, have been implicated in field outbreaks of pigs, cattle and chickens. The most frequently observed effect of DON in farm animals is feed refusal resulting in reduced performance. In the field, concentrations as low as 1 mg/kg have been associated with feed refusal in pigs, which is the most sensitive animal. More typically concentrations of >2–5 mg/kg are required for decreased feed intake and reduced weight gain and concentrations of >20 mg/kg diet for vomiting and feed refusal in ruminants (Pitt *et al.*, 2012). Dogs and cats are also sensitive to the emetic effects of DON.

Zearalenone

Zearalenone (ZEA) is a non-steroidal estrogenic mycotoxin produced by several *Fusarium* species, but primarily by *F. graminearum* (teleomorph *G. zeae*) and *F. culmorum*, in maize and small grains (wheat, oats, barley, rye, sorghum, millet, and rice). Contamination of grains and silage usually comes from the infection of stems, stalks and heads before harvest, but may also occur at post harvest if the crop is not dried properly. Low levels of the ZEA reduced derivatives α -zearalenol (α -ZEOL), which exhibit increased estrogenic activity, and β -zearalenol (β -ZEOL) of about the same potency of ZEA, have been identified in corn, corn by-products, corn silage and soya meal (Schollenberger *et al.*, 2006). The same ZEA-producing species also produce the trichothecene toxin DON and in maize have been found in association with the endophytic fumonisin-producing species *F. proliferatum*. Therefore, grain lots contaminated with ZEA are frequently also contaminated with DON and, in corn, sometimes also with FUMs (Ali *et al.*, 1998; Doko *et al.*, 1996). ZEA mimics the reproductive hormone estrogen and has high affinity for estrogen receptors, causing reproduction and fertility disorders, known as estrogenism, in sensitive animals. A synthetic analog of ZEA, called zeranol was marketed as an anabolic agent for growth promotion of sheep and cattle. Zeranol is now banned in Europe.

Experimentally, ZEA treatment increased incidences of liver cell and pituitary tumors in mice but not in rats. To date, the human health effects remain largely undefined. Based on the currently available data, IARC has categorized ZEA as Group 3, not carcinogenic to humans (International Agency for Research on Cancer IARC, 1993). Swine are the most commonly affected farm

animals. Pre-pubertal female pigs are the most susceptible animal to the estrogenic effects of ZEA. The sensitivity of pigs may be due to a higher affinity of their estrogen receptors for α -ZEOL that is formed in the liver and in the intestines by metabolism of ZEA. Cattle and sheep are much less sensitive than pigs, and poultry are regarded as resistant. The clinical effects of zearalenone may include an enlarged uterus, swelling of the vulva and vagina (known as vulvovaginitis), enlarged mammary glands, anestrus (periods of infertility), and abortion. ZEA may be passed to nursing piglets through the mother's milk. Field outbreaks of estrogenic syndrome in pigs have been reported in North America, Europe, Africa, Asia, and Australia (Zinedine *et al.*, 2007).

Co-Occurrence of Mycotoxins

While regulations enforced by various countries have set the limits for the content of individual mycotoxins or total congeneric mycotoxins (e.g., aflatoxins) in food and feed, contamination with only one single mycotoxin is the exception rather than the rule. More frequently, two or more mycotoxins co-occur simultaneously, especially in feed. As a matter of facts, many mycotoxigenic fungi are able to produce different mycotoxins at a time; in addition, commodities can be contaminated by different mycotoxigenic fungi, and feeds are usually made by mixtures of various commodities, each of which can be contaminated with different mycotoxins. A three-year worldwide survey indicated that 48% of 7049 analyzed feedstuffs samples were contaminated by two or more mycotoxins (Rodrigues and Naehrer, 2012). With regard to the major regulated mycotoxins (Afls, DON and other trichothecenes, ZEA, FUMs, and OTA), a survey of the literature concerning the co-occurrence in cereals and cereal-derived products, resulted in 127 different mycotoxin combinations reported (Smith *et al.*, 2016). The combinations Afls + FUM, DON + ZEA, Afls + OTA, and FUMs + ZEA were the most frequently reported. Although the significance is limited by the low numbers of literature data, the following combinations have also been reported: Afls + OTA on herbs and spices, Afls + OTA in dried fruits, and combinations of different trichothecenes in oilseeds (nuts, tree nuts, soy, olives) (Smith *et al.*, 2016). In cereals and meat products, OTA more or less frequently co-occurs with minor *Aspergillus* and *Penicillium* mycotoxins such as citrinin, and penicillic acid, which also possess nephrotoxic and carcinogenic activity, with Afls or with the *Fusarium* mycotoxin FB₁ (Šegvić Klarić *et al.*, 2013).

Since most studies have focused on the occurrence and toxicology of a single mycotoxin, the health risk from this multi-exposure is not well-characterized. The exposure to multiple mycotoxins may lead to additive, synergistic or antagonistic toxic effects that cannot be always predicted based on the individual toxicities (Grenier and Oswald, 2011). Most studies have been based on in vitro experiments in cell models of human and animal origin, mostly using binary mixtures of mycotoxins. The results of these experiments are not always consistent, and different effects were reported for one particular combination, depending on the used cell model, the test concentration, the time of exposure and the ratio of mycotoxins in the combination. For instance, Alassane-Kpembé *et al.* (2013, 2015) reported that DON in combination with its acetylated derivatives (3-AcetylDON and/or 15-AcetylDON) resulted in synergistic cytotoxicity at low inhibitory concentration levels (Alassane-Kpembé *et al.*, 2013) and in additive effects at higher doses (Alassane-Kpembé *et al.*, 2015). As for the most common trichothecene combination DON + NIV, different effects (synergistic, additive or antagonistic) have been reported by different authors, depending on the cell line and test concentration (Alassane-Kpembé *et al.*, 2013, 2015; Marzocco *et al.*, 2009; Wan *et al.*, 2013). Likewise, variations of the effects depending on the model and tested concentrations were reported also for the mixtures of fusariotoxins DON + FUS-X and NIV + FUS-X + FUS-X (Alassane-Kpembé *et al.*, 2013, 2015), DON + T2 and DON + beauvericin (BEA) (Ruiz *et al.*, 2011; Ficheux *et al.*, 2012). With regard to another very common combination, DON + ZEA, Kouadio *et al.* (2007) and Ficheux *et al.* (2012) found additive cytotoxicity on Caco-2 and CFU-GM cell lines respectively, whereas Wan *et al.* (2013) and Bensassi *et al.* (2014) reported antagonism on IPEC-J2 and human HCT116 cells, respectively. Concerning the mixtures involving ZEA, FB₁ and emerging mycotoxins such as BEA and enniatins (ENNs), the majority of reports suggest antagonistic or additive cytotoxic effects (Smith *et al.*, 2016). Most of the studies addressing the effects of OTA + PAT, OTA + FB₁, and OTA + Afls combinations have shown additive or synergistic interactions. However, less than additive and antagonistic interactions were also observed particularly for the OTA + Afls combination (Šegvić Klarić *et al.*, 2013). The picture is even more complex when ternary, quaternary or multiple combinations are considered.

At the whole, from the knowledge currently available, it's not possible to draw definitive and solid conclusions about the toxic effects of co-occurring mycotoxins and hence regulations throughout the world currently do not take the effects of mixtures of mycotoxins into account. Nevertheless, it is nowadays apparent that the regulated mycotoxins often co-occur and interact toxicologically with each other and also with other less studied compounds, such as masked and emerging mycotoxins (Ficheux *et al.*, 2012). In general, most of the mycotoxin mixtures lead to additive or synergistic effects, highlighting both a significant threat to human and animal health and a critical regulatory issue that needs to be addressed urgently.

Modified (Masked) Mycotoxins

Mycotoxigenic fungi produce mycotoxins in living plants during the infection process. In turn, plants can metabolize compounds produced by plant pathogens, including mycotoxins, as a mechanism of self-defense. Plant metabolites of mycotoxins are called masked mycotoxins (Berthiller *et al.*, 2013). Detoxification of metabolites produced by plant pathogens involves the chemical transformation of toxic compounds by plant enzymes (Phase I), followed by the covalent binding of phase I activated metabolites

(Phase II) that results in products with reduced or no toxicity (Coleman *et al.*, 1997). Phase I reactions usually involve hydrolysis or oxidation and are typical for lipophilic toxins, while most of the hydrophilic compounds are not affected by this phase. Hydrolysis in phase I is catalyzed by esterases and amidases; oxidations are in the majority of cases catalyzed by the cytochrome P-450 system (Coleman *et al.*, 1997). The reaction product of phase I are not necessarily less toxic than the parent compounds and in some cases the plant metabolite may be as toxic or even more toxic than the parent compound. In phase II, the plant enzymes catalyse the covalent binding of hydrophilic phase I-generated metabolites with different residues, including glucose, malonic acid and glutathione (GSH, γ -glutamyl-cysteinyl-glycine) (Coleman *et al.*, 1997). Glucosyl residues conjugate with hydroxy, thiol, amino and carboxy groups. Malonyl residues conjugate with hydroxyl and amino groups. GSH residues have an affinity with electrophilic sites in the molecule. These phase II reactions are catalyzed by glucosyl-, malonyl- and glutathione-S-transferases (GSTs), respectively. Phase II products are usually either non-toxic or less toxic than the parent compounds. Finally, the phase II toxic metabolites are either excreted from the plant cytosol via membrane-bound transporters into the apoplast or compartmentalized into the vacuolar space. The phase III of plant detoxification involve sequestration of compounds conjugated to glucose or GSH into the vacuole or the irreversible binding to the cell wall. In this way, detoxification products are permanently stored in the plant tissue rather than excreted. The majority of toxins conjugated with GSH are compartmentalized in the vacuole, where the conjugates may undergo further transformations.

Plant metabolites have been described for some regulated mycotoxins, including the *Fusarium* mycotoxins DON, ZEA FUMs, NIV, FUS-X, T-2, HT-2 and the *Aspergillus* and *Penicillium* toxins OTA and PAT (Berthiller *et al.*, 2013). The modified mycotoxins are not detected by the common analytical methods utilized for assessment of crop and food contamination, because of the mycotoxin structure modification. Therefore, the extractable conjugated or nonextractable bound mycotoxins remain in the plant tissues and, although potentially harmful, they are neither routinely searched, nor regulated by law. Toxicological data on modified mycotoxins are still scarce, but several studies suggest that a potential threat to food safety may come from these substances (Gratz, 2017; Zhang *et al.*, 2020). Conjugation of mycotoxins with epoxides, lactones or aldehyde groups are mostly irreversible, but conjugation to glucose can be reversed by the glycosidase enzymes present in plants and/or in the digestive system of animals and are, therefore, of higher concern for food and feed safety. To date, only metabolites of some fusariotoxins have been found to occur in natural conditions. Particularly, glycosylated forms of DON, T-2, HT-2, NIV, ZEA, ZEOLs have been proven to occur in naturally infected cereals such as wheat, barley, oats and maize (Schneweis *et al.*, 2002; Berthiller *et al.*, 2009; Lattanzio *et al.*, 2012; Nathanail *et al.*, 2015), mostly co-existing with free forms. Currently, deoxynivalenol-3- β -D-glucoside (DON-3G) is the most extensively studied masked mycotoxin. DON-3G has been reported to occur in cereal grains (wheat, maize, barley and oats) and cereal flours, as well as in cereal-derived processed products such as bread, snacks, biscuits, pasta (Vendl *et al.*, 2010; Desmarchelier and Seefelder, 2011), malt and beer (Kostelanska *et al.*, 2009), and in feeds (Kovalsky *et al.*, 2016). The European Food Safety Authority (EFSA) considers the toxicity of DON-3G to be similar to that of DON and, due to the large rate of transformation of DON-3G in DON during digestion, has suggested that DON-3G is added to the total DON exposure for risk assessment. A tolerable daily intake (TDI) of 1 μ g/kg body weight/day for the sum of DON, 3-acetyl-DON, 15-acetyl-DON and DON-3G has been recommended for chronic exposure of humans (European Food Safety Authority EFSA, 2017).

A few studies have demonstrated the presence of zearalenone-14- β -D-glucoside (ZEA-14G, a.k.a. zearalenone-4- β -D-glucoside), a metabolite of the estrogenic mycotoxin ZEA, in crop plants (Schneweis *et al.*, 2002). ZEN-14G and the ZEOLs derivatives α -zearalenol-14- β -D-glucoside (α -ZEOL-14G) or β -zearalenol-14- β -D-glucoside (β -ZEOL-14G) have been found in grains and cereal-based foods (De Boevre *et al.*, 2013; Nathanail *et al.*, 2015). Another ZEA metabolite, namely zearalenone-14-sulfate (a.k.a. zearalenone-4-sulfate) has been identified in a survey of different cereal-based products (wheat flour, whole-meal wheat bread, maize meal, biscuits, wheat flakes, bran flakes, muesli, crackers, cereal snack bars and polenta), although only in 13 out of 84 analyzed samples and at low concentrations, ranging from <1–6.1 μ g/kg (Vendl *et al.*, 2010).

Emerging Mycotoxins

Besides the regulated mycotoxins, there is a number of other fungal toxic compounds produced by spoilage agents which are neither routinely determined, nor legislatively regulated because of their lesser occurrence or uncertain toxicity in vivo. Some of these metabolites are produced by the main mycotoxigenic species and are often co-occurring with regulated mycotoxins. The term “emerging mycotoxins” is used for such compounds. Emerging mycotoxins may contribute to the overall health risk of the contaminated commodities, either because of their direct toxic effects or because of biological interaction with other mycotoxins, in additive or synergistic manner. Currently there are no regulations enforced that set standards for the presence of these mycotoxins in foods, since the available information about their occurrence, levels of contamination and toxicity is not sufficient to proof health risks for humans and animals. Lately, more research efforts have been done to assess the health risks they actually pose. The increasing diffusion of analytical methods based on liquid chromatography – mass spectrometry (LC-MS) that allow the sensitive and fast simultaneous determination of multiple fungal metabolites in various matrices is expected to provide more information about the occurrence and co-occurrence of emerging mycotoxins in foods and feeds (Tittlemier *et al.*, 2019).

Emerging *Fusarium* Mycotoxins

The most significant and frequently occurring emerging mycotoxins are produced by *Fusarium* spp. The main mycotoxins in this group are enniatins (ENNs), beauvericin (BEA), fusaproliferin (FP) and moniliformin (MON).

Enniatins and beauvericin

A recent study showed that BEA was the emergent mycotoxin with the highest prevalence in feed and feed ingredients, followed by ENNs (Streit *et al.*, 2013). ENNs and BEA are structurally and mechanistically similar molecules that are biosynthesized by the non-ribosomal multifunctional enzymes enniatin and beauvericin synthetases, hybrid enzymes of a peptide synthetase and an integrated N-methyltransferase. They are cyclic hexadepsipeptides consisting of three D- α -hydroxy-isovaleryl-(2-hydroxy-3-methylbutanoic acid) alternating with three amino acid units. In BEA, the three amino acid residues are aromatic N-methyl-phenylalanines, whereas in the enniatins of type A and B the amino acid residues are aliphatic N-methyl-valine or-isoleucine or mixtures thereof. BEA was first isolated from the culture of the entomophagous fungus *Beauveria bassiana* and is produced by various *Fusarium* species, including *F. proliferatum* and *F. temperatum* (Logrieco *et al.*, 1998; Jestoi, 2008). ENNs, originally discovered from cultures of *F. orthoceras* var. *enniatum* (later renamed *F. oxysporum*) are produced by several *Fusarium* species, including *F. avenaceum*, *F. sambucinum*, *F. poae*, *F. sporotrichioides* and *F. tricinctum*, which infect cereals and other commodities.

The primary toxic action of BEA and ENNs is thought to be related to their ionophoric properties; they can form stable and lipophilic complexes with cations and transport them into lipophilic matrices such as cell membrane, resulting in disturbances of the cell osmotic balance. In addition, both ENNs and BEA form cation-selective channels in cell membranes, which impair the membrane functions (Kouri *et al.*, 2003; Kamyar *et al.*, 2004). ENNs and BEA exhibit a number of different toxic effects in vitro, but toxicity in vivo is generally low; this is thought to be due to their rapid metabolization rather than low bioavailability.

ENNs have antimicrobial, phytotoxic and insecticidal properties and low micromolar concentrations were shown to be cytotoxic to different animal cell lines (mouse macrophages, porcine kidney cells, *Spodoptera frugiperda* SF-9 cell line), and to reduce the motility of boar spermatozoa. Cell death was shown to be mediated by the induction of apoptosis via the mitochondrial pathway (Tonshin *et al.*, 2010) or by the induction of necrosis linked to lysosomal damage (Ivanova *et al.*, 2012). Several studies investigated the in vivo toxicity of ENNs in rodents. Most of these studies showed low toxicity. A single dose of 50 mg ENNs/kg body weight did not induce signs of toxicity in rats (Bosch *et al.*, 1989). Twenty-nine forms of ENNs are known (Sy-Cordero *et al.*, 2012), but ENNs A, A1, B, and B1 are the most frequently detected in food. In a survey of the occurrence of ENNs in Europe in the years 2000–2013, ENNs were detected in 37%, 68%, and 76% of food ($n = 4251$), feed ($n = 3640$), and unprocessed grain ($n = 2647$) samples (European Food Safety Authority EFSA, 2014). Maximum reported concentrations in grains were 950, 2000, 18,300, and 5720 $\mu\text{g/kg}$ for ENN A, ENN A1, ENN B, and ENN B1, respectively. Based on these data, EFSA concluded that acute exposure to ENNs is not a concern to human health.

Antimicrobial activity against Gram (+) bacteria, cytotoxicity to human (e.g., HeLa, HEP G2, IARC BL-41, U937), animal (e.g., murine tumor, mouse macrophages, porcine kidney) and insect (e.g., SF-9) cell lines and pro-apoptotic effects (Wätjen *et al.*, 2014) in in vitro tests have been reported for BEA (Mallebrera *et al.*, 2018). BEA was not mutagenic in the Ames test (Fotso and Smith, 2003). In vivo, the reported LD₅₀ values of BEA in mice were ≥ 100 and ≥ 10 mg/kg for oral and intraperitoneal (i.p.) administration, respectively (Omura *et al.*, 1991). In a survey of the occurrence of BEA in Europe in the years 2000–2013, BEA was detected in 20%, 21%, and 54% of food ($n = 732$), feed ($n = 861$), and unprocessed grain ($n = 554$) samples. Maximum concentrations for BEA determined in grains and in cereal-based food were 6400 and 844 $\mu\text{g/kg}$, respectively (European Food Safety Authority EFSA, 2014). In their scientific opinion, the EFSA concluded that acute exposure to BEA is not a concern to human health. BEA was also found to occur with high frequency (98% of 83 analyzed samples) in feed and feed raw materials samples, with maximum concentrations of 2330 $\mu\text{g/kg}$ (Streit *et al.*, 2013), and in Chinese medicinal herbs (20% of 60 samples) with a maximum concentration of 125 $\mu\text{g/kg}$ (Hu and Rychlik, 2014).

To date, no conclusion has been drawn with respect to health risk associated to chronic exposure to ENNs or BEA, due to insufficient data on their in vivo toxicity.

Fusaproliferin

FP is produced by a limited number of *Fusarium* species, most notably by the members of the *Gibberella fujikuroi* species complex, such as *F. proliferatum* and *F. subglutinans*. High levels of FP occasionally occur in grains and grain-based food and feed. However, toxicity and mode of action of FP have not been thoroughly investigated, so far. FP is moderately cytotoxic to lepidopteran SF-9 cells and to human B lymphocyte IARC/LCL 171 cells (Logrieco *et al.*, 1996). In vivo, FP has been found to be toxic in the brine shrimp (*Artemia salina*) larvae bioassay, an invertebrate model often used for studies of zootoxicity of mycotoxins and of environmental toxicology, with a level of toxicity (50% lethal dose, LD₅₀ = 53.4 μM or 23.7 $\mu\text{g/mL}$) comparable to that of some other mycotoxins such as AFB₁ and DON (Logrieco *et al.*, 1996). FP exerted teratogenic and pathogenic effects on chicken embryos when applied at concentrations of 1 or 5 mM (Ritieni *et al.*, 1997a). FP has been found in grains and grain-based foodstuffs (Santini *et al.*, 2012), at concentrations that in maize may be as high as 500 mg/kg (Ritieni *et al.*, 1997b). FP was detected in 17% of samples ($n = 83$) of feed and feed raw materials with median and maximum concentrations of 2.6 and 14.8 mg/kg, respectively (Streit *et al.*, 2013). FP has been found to co-occur with BEA, FB₁ and FB₂ in maize from Europe, USA and South Africa (Ritieni *et al.*, 1997b; Munkvold *et al.*, 1998; Shephard *et al.*, 1999).

Moniliformin

MON was first isolated in 1973 from cultures of a *Fusarium moniliforme* isolate which was later identified as *F. proliferatum*. The list of MON-producing species includes *F. acuminatum*, *F. avenaceum*, *F. fujikuroi*, *F. oxysporum*, *F. proliferatum*, *F. sambucinum*, *F. subglutinans* and *F. tricinctum* (Jestoi, 2008). MON is an organic acid that in nature exists as sodium or potassium salt and is therefore strongly water-soluble. The primary mode of action of MON seems to be the interference with the tricarboxylic acid cycle by inhibition of thiamin pyrophosphatase dependent enzymes and of several other enzymes sharing thiamin as common cofactor (pyruvate dehydrogenase, α -ketoglutarate dehydrogenase, pyruvate decarboxylase, and acetohydroxy acid synthase) (Pirrung *et al.*, 1996). The authors suggested that MON functions as an active site-directed, irreversible affinity label for enzymes utilizing thiamin. MON was phytotoxic to wheat, tobacco and maize; it mostly showed low levels of cytotoxicity in vitro, except in lymphocytes, skeletomyocytes and cardiomyocytes (Jestoi, 2008), possibly due to the limited penetration of the hydrophilic molecule through the cell membrane. MON was not mutagenic in the Ames test indicating that it is not a genotoxic carcinogen (Knassmüller *et al.*, 1997). However, a study that investigated the genotoxic effects of MON on human peripheral blood lymphocytes, reported chromosomal aberrations, sister-chromatid exchanges, and micronucleus frequencies significantly increasing in a dose-dependent manner after treatment of lymphocytes with MON concentrations between 2.5 and 25 μ M (Celik *et al.*, 2009). MON shows more severe effects in vivo, with birds and mink being the most sensitive animals to both oral and i.p. administrations (Jestoi, 2008). The main symptoms of acute moniliformin toxication are muscular weakness, respiratory stress, myocardial degeneration, accompanied by histopathological changes in organs such as the kidneys, the lungs and the pancreas and ultimately coma and death (Kriek *et al.*, 1977). Some in vivo studies with broiler chickens and turkey poultries fed with MON-contaminated culture material suggest that MON may have immunosuppressive effects (Li *et al.*, 2000a,b). MON has been found to occur in maize and maize-based products in South Africa, EU, UK, China, and Switzerland (Jestoi, 2008) in concentrations as high as 530 mg/kg of *Fusarium*-damaged kernels (Lew *et al.*, 1996). Occurrence of MON in cereal grains (wheat, rye, oats, barley) and cereal based products is also frequent in various regions of the world, albeit at lower levels than in maize (Jestoi, 2008).

Emerging *Aspergillus* and *Penicillium* Mycotoxins

The genus *Aspergillus* comprises more than 300 species and is characterized by a high level of chemodiversity. Besides AflTs, OTA, FUM and PAT, a number of other toxic substances have been isolated from *Aspergillus* spp. (Wilson, 1966; Varga *et al.*, 2015). Of major interest as possible food and feed contaminants are sterigmatocystin (STE) and cyclopiazonic acid (CPA).

STE is a precursor of aflatoxin biosynthesis produced by many *Aspergillus* species belonging to the sections *Versicolores*, *Usti*, *Aenei*, *Ochraceorosei*, *Cremeri* and *Nidulantes* of the genus. While aflatoxin producing species in the section *Flavi* do not accumulate sterigmatocystin, which is efficiently converted to aflatoxins, species belonging to the sections *Ochraceorosei* and *Nidulantes* produce AflTs and STE simultaneously (Samson *et al.*, 2014). The main producers of STE are *A. flavus*, *A. parasiticus*, *A. nidulans*, and, most importantly, *A. versicolor* and its related species (EFSA, 2013). The toxic effect of STE is mediated by its furofuran ring structure, which forms DNA adducts after metabolic activation to an epoxide (Wang and Groopman, 1999). STE exerts genotoxic and cytotoxic effects on different cell lines, e.g., immortalized ovarian hamster cells (CHO-K1 cells; Zouaoui *et al.*, 2016), liver hepatocellular cells (HepG2; Gao *et al.*, 2015), and human lung adenocarcinoma cells (A549; Bünger *et al.*, 2004). STE is classified by IARC as a group 2b carcinogen (possibly carcinogenic to humans; IARC, 1987). In vivo studies have been carried out in livestock, fish, and other animals. Whereas the in vivo effects of STE are similar to those of AflB₁, its acute toxicity is much lower. Studies in ruminants found harmful effects of a STE-contaminated diet in cattle (Vesonder and Horn, 1985), but not in sheep (Böhm and Sayed, 1994). Data on the natural occurrence of STE are sparse. STE was found to occur in green coffee beans, spices, nuts, cereal grains, beer, and the outer layer of hard cheese colonized by *A. versicolor* (Versilovskis and De Saeger, 2010). The JECFA is currently working on a safety assessment of STE, following the recommendation of the Codex Committee on Contaminants in Foods (JECFA, 2015).

CPA is an indol-tetramic acid biosynthesized by a hybrid polyketide synthase-nonribosomal peptide synthetase (PKS-NRPS) enzyme from tryptophan, mevalonate, and two molecules of acetate. It was originally isolated from *Penicillium cyclopium*. While the main producers of CPA are *Penicillium* spp. (e.g., *P. camemberti*, *P. chrysogenum*, *P. griseofulvum*, *P. urticae*; Frisvad *et al.*, 2004), it can be produced also by *Aspergillus* species in the section *Flavi*, including *A. flavus* and *A. oryzae*, and by *A. versicolor* (section *Versicolores*) and *A. lentulus* and *A. fumisynnematus* (section *Fumigati*, Varga *et al.*, 2011). CPA is a potent, specific, and reversible inhibitor of Ca²⁺-activated ATPase in cell sarcoplasmic and endoplasmic reticulum (Plenge-Tellechea *et al.*, 1997). This mode of action has been demonstrated in various tissues and cells, including smooth, skeletal, and cardiac muscle, cultured renal epithelial cells, rat thymic lymphocytes, murine peritoneal macrophages, guinea pig ureter, and many others (Burdock and Flamm, 2000). In muscle tissues, the effect of CPA results in negative inotropic and chronotropic alterations that become apparent in the symptoms of CPA toxicity (Norred *et al.*, 1985). Chelation of such cations as calcium, magnesium, and iron may be also an important mechanism of toxicity of CPA. CPA is not considered to be a potent acute toxin (for instance, its oral LD₅₀ in rodents is in the range of 30–70 mg/kg). Clinical signs of acute toxicity in mammals were similar in all studies and include ptosis, hypokinesia, ataxia, hypothermia, action tremor, convulsions, and cessation of food and water intake. The chronic toxicity of CPA has been investigated in many animal species, including chicken, rabbit, dog, pig, and rat (Burdock and Flamm, 2000). Effects of ingestion of CPA-contaminated food include severe gastrointestinal distress and neurological disorders and the digestive tract, liver, kidney and heart, show degenerative changes and necrosis. Since CPA is produced by several molds that commonly occur on agricultural commodities or that are used in certain food fermentations, such as some *Penicillium* species which are used in the production of

fermented sausages in Europe or *P. camemberti* used to produce Camembert cheese and *A. oryzae* used to produce fermented soy sauces, its occurrence warrants attention. CPA may occur naturally in corn and peanuts and in a type of millet (kodo) that reportedly caused human intoxication in India. Few mycotoxicoses attributable to CPA have been reported so far, primarily because of the benign nature of the intoxication. It was suggested that CPA was involved along with AFTs in the Turkey X disease in the United Kingdom in 1960.

Emerging *Alternaria* Mycotoxins

Alternaria is an ubiquitous fungal genus belonging to the division *Ascomycota*, which comprise about 300 described species. Several *Alternaria* spp. (e.g., *A. alternata*, *A. tenuissima*, *A. solani*, and *A. infectoria*, the so-called black molds) are considered as both saprophytes and plant pathogens that can cause diseases of a number of agricultural crops, viz., cereals (wheat, barley, and sorghum), tomatoes, sunflower seeds, citrus fruits, apples, grapes, and olives, and considerable economic losses (Logrieco *et al.*, 2009). Due to the ability of *Alternaria* spp. to grow at low temperatures, fungal infection of crops may also occur at post-harvest, even if storage or transport are under refrigeration. *Alternaria* spp. may produce in moldy foodstuff metabolites that are mutagenic and genotoxic in vitro and that potentially represent a serious health risk for both humans and animals. The most important of the *Alternaria* toxins are alternariol (AOH), alternariol monomethyl ether (AME) and tenuazonic acid. (TeA). It is worth to mention that Schwarz *et al.* (2012) reported that AOH, AME, and TeA made only a minor contribution to the genotoxicity of *A. alternata* extracts. Based on this finding, other metabolites (e.g., alt toxins) or not yet identified compounds may also be important for the assessment of the health risk associated to *Alternaria* food spoilage.

In vitro, AOH and AME were shown to be cytotoxic to human HeLa and colon carcinoma cell lines (Pero *et al.*, 1973; Bensassi *et al.*, 2012). Cytotoxicity appears to be mediated by the activation of the mitochondrial pathway of apoptosis (Bensassi *et al.*, 2012). AOH and AME induced DNA strand breaks and chromosomal aberration in different cell lines (Pfeiffer *et al.*, 2007). Also, AOH induced oxidative stress that resulted in oxidative DNA damage (Fernandez-Blanco *et al.*, 2015) and was shown to be mutagenic in mammalian cell lines (Brugger *et al.*, 2006). A slightly estrogenic potential of AOH was detected in a human endometrial adenocarcinoma cell line and synergistic estrogenic effects of AOH in combination with ZEN or its metabolite α -ZEOL were reported (Vejdovsky *et al.*, 2017). AOH and AME specifically inhibited progesterone secretion in cultured porcine granulosa cells, which suggests that these mycotoxins may affect the reproductive performance of pigs and, possibly, of other mammalian species (Tiemann *et al.*, 2009). Studies on in vivo toxicity of AOH or AME generally have resulted in no evidence of toxicity after oral administration, in chicken, rats and mice (Ostry, 2008). An in vivo study of AOH toxicokinetics revealed the toxin undergo low systemic absorption and rapid metabolism, and therefore the target organ toxicity is likely restricted to the gastrointestinal tract (Schuchardt *et al.*, 2014). In 2011 EFSA opinion concluded that the estimated chronic dietary exposure of humans to AOH and AME exceeds the threshold of toxicological concern for potentially genotoxic substances (EFSA, 2011). However, administration of high doses of the toxins did not elicit toxic or genotoxic effects in in vivo models. Nevertheless, the significant genotoxic potential shown in in vitro tests warrants more investigation of in vivo toxicity of AOH and AME.

TeA is produced by *Alternaria* species that grow on vegetables, fruits, and cereals (e.g., *A. alternata*, *A. tenuissima*, *A. citri*, *A. mali*, *A. oryzae*, *A. solani*) and by the plant pathogenic fungi *Phoma sorghina* and *Magnaporthe oryzae* (anamorph *Pyricularia oryzae*) (Ostry, 2008). The toxic effect of TeA seems to be due to its interference with protein biosynthesis (Shigeura and Gordon, 1963). The compound was not mutagenic in the Ames test (Schrader *et al.*, 2006). In vivo, TeA was toxic to mice, rats, dogs and monkeys, and observed symptoms included diarrhea, muscle tremor, vomiting, and hemorrhages and, in some cases, death (Woody and Chu, 1992). Feeding broilers with feed contaminated with TeA at levels of 10 mg/kg for 3 weeks or daily oral administration of ≥ 1.25 mg/kg of body weight to broilers and layers caused lesions in different organs and decreased weight gain and feed efficiency (Giambone *et al.*, 1978). Sorghum grain colonized by *Phoma sorghina* that contained TeA was associated with the human hematological disorder known as "Onyalai" (Bottalico and Logrieco, 1998). High levels of TeA (up to 1200 μ g/kg) were found in Sorghum-based infant food (Asam and Rychlik, 2013). In 2011, based on a survey of literature, EFSA concluded that the dietary exposure estimate for TeA is lower than the relevant threshold of toxicological concern value and therefore TeA is unlikely to be a human health concern (EFSA, 2011). However, some risk seems to exist for chickens and for infants consuming Sorghum-based food.

Control and Management of Mycotoxins

Mycotoxigenic fungi can be roughly classified into "field fungi" (black aspergilli, fusaria, ergot) and "storage fungi" (aspergilli, penicillia), based on their ecological requirements for growth. Field fungi infect crops and produce mycotoxins primarily before harvest. Storage fungi, which have the capability to grow at low water activities and temperatures, colonize the commodities mainly after harvest, during storage, transportation, or processing. Some fungi, such as *A. flavus*, belong to both classes and may colonize the agricultural products both before and after harvest. Measures of control and management of mycotoxigenic fungi and mycotoxins can be put into effect along the whole food or feed chains; while the pre harvest management strategies aim mainly at prevention of infection and contamination of crops, the post-harvest strategies include prevention, remediation and surveillance practices. Surveillance include regulation and monitoring of mycotoxins in food- and feedstuffs in order to avoid that already contaminated commodities are consumed as such and are, instead, properly discarded, detoxified or diverted to alternative uses.

Finally, dietary interventions can be applied to reduce the livestock intake of mycotoxins with diet by reducing mycotoxin bioavailability or by degradation of mycotoxins to not toxic or less toxic compounds in animal's gastrointestinal tract.

Pre-Harvest Interventions

The pre-harvest approach consists of strategies designed to reduce crop infection by mycotoxigenic plant pathogens. These interventions include breeding of resistant plant cultivars, application of good agricultural practice, and crop protection by chemical pesticides or biological control. In recent years, there has been increasing interest in the development of information and communications technologies (ICT) tools for the prevention of mycotoxin outbreaks based on weather forecasting data monitoring systems associated to prediction models. These tools would support decision making about appropriate interventions that need to be enforced when weather conditions are favorable to fungal/mycotoxins outbreaks. Both empiric and mechanistic models have been used to predict mycotoxin contamination in crops, with a prevalence of the former. The empiric approach describes the relation between the driving variables (i.e., rain during flowering) and the event of interest, that is mycotoxin contamination in grain at harvest, using statistical analysis. On the contrary, predictions of mechanistic models are based on mathematical functions that describe the relationship between driving variables and the different steps of fungal infection cycle (i.e., sporulation, infection or toxin production), which functions are developed mainly by trials in controlled conditions. Forecasting systems have been experimented for *Fusarium* toxins (DON, T-2 and HT-2) in wheat and for FUMs and AfTs in maize (Battilani, 2016). Minor efforts have been devoted to AfT contamination in nuts. AfloMan is a forecasting system for the formation of aflatoxin in groundnuts, in use in Australia.

Breeding crop plants for resistance to mycotoxigenic fungi is a straightforward strategy for reduction of contamination before harvest. The problem of ergot contamination of cereals and millets has been successfully minimized in the past by cultivating varieties of rye, wheat and pearl millet that are resistant to the disease. However, the genetics of resistance to other mycotoxigenic fungi is complex, and high levels of resistance are not yet available in high-yielding commercial cultivars. Maize hybrids and wheat and barley varieties with at least partial resistance to mycotoxin-producing fungi are currently available, but the commercial breeding process involves significant technologies and cost, which raise questions of access and affordability for low income countries. Resistance to *A. flavus*, especially in nut crops and oily seeds, has been studied. However, the development of commercial cultivars that are less subjected to *A. flavus* infections or aflatoxin accumulation encounters hurdles, because of lack of resistant genotypes in some crop species (e.g., cotton), long time required for breeding programs and questionable stability of the resistance conferred by the currently available genes (Rajasekaran *et al.*, 2006). Improved resistance to drought, insect damages, or other abiotic and biotic stresses that predispose plants to pre-harvest formation of aflatoxin have been experimented in groundnuts and maize. Infection of maize kernels by *F. verticillioides* and *A. flavus* is enhanced by insect injury; the resistance to insects of transgenic *Bt* hybrids that express one of the insecticidal proteins from the bacterium *Bacillus thuringiensis* has resulted in reduced fumonisins and, less consistently, aflatoxins levels in maize kernels (Munkvold, 2003), but transgenic approaches are not universally accepted. Leaving *Bt* hybrids apart, differential resistance to aflatoxin contamination among corn hybrids has been found (Windham and Williams, 1998). This, along with significant advances in the identification of natural resistance mechanisms and traits (Brown *et al.*, 2001) have prompted breeding programs aiming at enhancing maize resistance to aflatoxin. However, resistance to aflatoxin contamination involves multiple chromosome regions and several genes. Therefore, selection for resistance, while maintaining essential agronomic characteristics, has been slow.

Wheat cultivars with reasonable resistance to *Fusarium* head blight (FHB) and accumulation of DON and, secondarily, of ZEA are in use in the USA, Canada, and Europe. Trichothecenes have been reported to act as virulence factors that contribute to the virulence of *Fusaria* to wheat and maize (Desjardins *et al.*, 1996). Hence, increased plant resistance to the toxins would result in increased plant resistance to the pathogen. However, a direct relationship between resistance to FHB and resistance to toxin contamination of the infected grain remains a subject of controversy. Although generally the higher the resistance of a genotype to FHB the lower the toxin accumulation, varieties with low FHB severity and high DON content, and vice versa, have also been described (Mesterházy *et al.*, 1999). No FHB resistant varieties are yet commercially available for durum wheat, but different sensitivities to trichothecenes type B accumulation was demonstrated among lines of *Triticum turgidum* subsp. *durum* which showed only slight differences in the levels of fungal infection (Favre *et al.*, 2004). Those wheat lines may contain endogenous compounds able to either inhibit trichothecene biosynthesis or to degrade or modify the toxins. In wheat, the resistance to FHB can be categorized into five types: type I resistance that operates against initial infection; type II resistance that operates against the spread of the pathogen within the host; type III that is the ability to resist to kernel infection; type IV that is tolerance to infection; and type V resistance to DON accumulation (Boutigny *et al.*, 2008). Type V resistance to *Fusarium* can be subdivided into two classes. Class 1 includes mechanisms by which the plants degrade or detoxify trichothecenes. This includes glycosylation, a natural process already reported in wheat (Berthiller *et al.*, 2005), and two other detoxification processes, acetylation and de-epoxidation. Detoxification by glycosylation in wheat has also been described for zearalenone (Schneweis *et al.*, 2002). Acetylation is a detoxification process used by *Fusarium* species to protect themselves from their own toxins. Kimura *et al.* (1998) isolated from *F. graminearum* the Tri101 gene, which encodes a trichothecene 3-O-acetyltransferase able to convert trichothecenes to less toxic derivatives. De-epoxidation activity has been found in bacteria of ruminal or intestinal flora and an epoxidase from a strain of *Eubacterium* sp. was able to enzymatically reduce different type A trichothecenes and deoxynivalenol to non-toxic de-epoxide metabolites (Fuchs *et al.*, 2002). These findings open the possibility of transgenic plants containing heterologous genes for

detoxification of trichothecenes, as shown in tobacco (Muhitch *et al.*, 2000), wheat and barley (Okubara *et al.*, 2000). However, the genes involved in the detoxification pathways mostly remain non-identified. Class 2 comprises mechanisms that lead to reduced mycotoxin accumulation by inhibition of their biosynthesis through the action of plant endogenous compounds. These include many plant compounds with antioxidant properties, like phenolic compounds, peptides or carotenoids, and with pro-oxidant properties, like hydrogen peroxide or linoleic acid-derived hydroperoxides, which have been described as “modulators” of mycotoxin biosynthesis. Trichothecenes are synthesized from trichodiene by a series of oxygenation reactions which require molecular oxygen. Therefore, changes in the oxidative status of the plant tissues can affect the secondary metabolism of the fungus and modulate the levels of trichothecene biosynthesis (Ponts *et al.*, 2006). A breeding strategy that combines both resistance to pathogen infection and toxin accumulation would probably lead to new wheat genotypes able to limit efficiently the occurrence of *Fusarium* mycotoxins.

Good Agricultural Practice (GAP) is the primary strategy to reduce mycotoxins in cereals and cereal based products. GAP consists of good farm management. In general, all the practices that reduce the biotic and the abiotic stresses of crops may be regarded as a part of a GAP strategy for prevention of mycotoxins. GAP includes planting at the appropriate time (to avoid high temperature and drought stress during the period of seed development and maturation) and with the right spacing, avoiding excess of watering and fertilization, control of weeds, cleaning from debris of preceding crop, crop rotation to reduce tiring of soil and soil pest population increase, and harvesting of crops at or before full maturity, since over-mature crops are more subjected to damages and hence fungal spoilage. Besides a general effect on plant vigor and health, these measures may also have a direct effect on survival, spread and infection of mycotoxigenic fungi. A code for GAP practices for the management of mycotoxins contamination in cereals has been issued by FAO/WHO (Codex Alimentarius, 2003). Wheat and maize have been found to be particularly susceptible to *Fusarium* species and they should not be used in rotation with each other. Crops such as potato, other vegetables, clover and alfalfa that are not hosts to *Fusarium* species should be used in rotation to reduce the inoculum in the field. FHB and maize ear rot are primarily initiated at the crop flowering season by the sexual spores (ascospores) of *F. graminearum* (*Gibberella zeae*) that are formed inside the fruit bodies (perithecia) of the fungus in the colonized stubble and then forcibly ejected up to plant heads. Therefore, the seed bed for each new crop should be prepared by plowing under or by destroying or removing old seed heads, stalks, and other debris that may have served, or may potentially serve as substrates for the growth and spread of mycotoxin-producing fungi. Excess precipitation during anthesis (flowering) makes conditions favorable for dissemination and infection by *Fusarium* spp.; thus irrigation during anthesis and during the ripening of the crops, specifically wheat, barley, and rye, should be avoided. Cereals should be harvested at full maturity, so that damage to the grain is minimized and moisture levels are lower than those conducive to mold growth during storage (generally 15%). Delayed harvest of grain already infected by *Fusarium* species may cause a significant increase in the mycotoxin content of the crop.

The use of pesticides for the control of mycotoxigenic fungi and the reduction of mycotoxins is controversial. Some in vitro studies have showed that fungicides might stimulate mycotoxin production when administered at sub-lethal concentrations (D’Mello *et al.*, 2001; Matthies *et al.*, 1999). In the field, the triazole fungicides metconazole and tebuconazole and the strobilurin fungicide azoxystrobin are effective against *Fusarium* species and FHB, but their use has resulted in inconsistent effects on DON contamination. In some field trials, the application of azoxystrobin resulted in an increase of DON content of grain (Simpson *et al.*, 2001). A biological approach for control of FHB and DON, consisting of the treatment of infected maize stalks with the microbial antagonists *Trichoderma atroviride* and *Clonostachys rosea* to reduce FHB in subsequently grown wheat has been recently experimented, with promising results (Gimeno *et al.*, 2020). Biocontrol of AFTs relies on competitive exclusion of toxin-producing *A. flavus* by a non-toxigenic strain of *A. flavus*. The non-toxigenic strains of *A. flavus* are strains incapable of producing AFTs because are defective for a polyketide synthase gene necessary for AFT biosynthesis (Ehrlich and Cotty, 2004). The non-toxigenic *A. flavus* strain is spread on the soil surface on a carrier substrate that permits growth of the fungus and the consequent production of high numbers of spores and, with time, it displaces the native aflatoxigenic genotypes by a mechanism of competition (Cotty, 2006). This method has proven to be successful in several instances, leading up to 80% reduction of aflatoxin contamination; it is currently utilized in cotton- and maize-growing areas of the USA, and also in Kenya and has led to the development of the commercial biopesticides AF36 (non-aflatoxigenic strain NRRL 18543) and Afla-Guard® (non-aflatoxigenic strain NRRL 21882).

Post-Harvest Interventions

After harvest, it is of utmost importance to observe good manufacturing practice (GMP), that is a range of practices that prevent fungal growth and hence reduce mycotoxin formation. GMP should be implemented during handling, storage, processing, and distribution of commodities for human food and animal feed (Codex Alimentarius, 2003). Drying and maintaining proper storage conditions are key elements for mycotoxin management at post-harvest. Immediately after harvest, moisture levels of the crop should be determined and, if necessary, it should be dried in such a manner that damage to the grain is minimized and moisture levels are lower than those required to support mold growth during storage (generally less than 15% for cereals). On the farm, a first cleaning can be done by removal of defects, including immature nuts or grains, infected and/or insect damaged kernels and weed seeds, debris, stones, soil, husks. Grain or nuts infected by mycotoxin-producing fungi often have visual symptoms or other physical characteristics that allow them to be separated from the healthy product. This can be done by hand sorting, air-screen cleaners, optical sorters, and density separation (Grenier *et al.*, 2014). Hand sorting of moldy, shriveled or insect-infested

nuts or kernels has proven to be an effective method of removing mycotoxin-contaminated food components without removing a large proportion of the product (Turner *et al.*, 2005; Van der Westhuizen *et al.*, 2011). The de-hulling of grains has been shown to reduce mycotoxin contamination significantly, since most of mycotoxins are concentrated in the grain pericarp (Siwela *et al.*, 2005). Washing methods are used to remove water-soluble mycotoxins from the outer surface of grains. Soaking maize in a 0.1 M sodium carbonate solution for 24–72 h can remove significant amount of DON, ZEA and FUM from kernels (Grenier *et al.*, 2014). A drawback of this method is that the grain must be dried before it can be stored.

After harvest, crops should be dried to safe moisture levels and cooled as quickly as possible. Freshly harvested commodities should not be left piling or heaping wet for more than a few hours prior to drying. Sun drying of some commodities in high humidity may result in fungal infection; forced air circulation to aerate the commodities and prevent high moisture and raise of temperature in the pile is advisable. The storage facility should be dry, well-vented and protected from rain, drainage or ground water. Where possible, grains and seeds should be aerated by circulation of air through the storage area to maintain proper and uniform temperature levels throughout the storage area. During the storage period, moisture content and temperature in the stored product should be checked at regular intervals or monitored by electronic systems; these climatic parameters have to be held below the critical levels determined for the storage of cereal grains, beans, and nut crops. Control of molds and pests with appropriate registered chemicals or with alternative methods should be applied if needed, in order to reduce fungal spoilage and pest damage. The use of suitable, approved preservatives (e.g., organic acids such as propionic acid) exclusively in grains intended for animal feed may be effective in killing various fungi and thus prevent the production of mycotoxins. Care must be taken because these compounds can negatively affect the taste and odor of grains. Appropriate measures for the protection of the commodity from inappropriate humidity and temperature levels, as well as from parasites and pests should be observed also during transportation. The mycotoxin levels along these passages should be monitored, using appropriate methods of sampling and analysis (Maragos and Busman, 2010; Tittlemier *et al.*, 2019). The above practices are usually implemented in developed countries, but can be very challenging in developing countries where adequate drying and storage facilities are not common.

Highly contaminated lots, containing mycotoxins at levels above the regulatory levels of tolerance, must be diverted from use as human food or feed for sensitive species. In the EU, the blending of contaminated batches with batches of good quality to lower the average mycotoxin content of the materials is prohibited (Verstraete, 2008). Remediation of contaminated commodities can still be achieved by thermal, biological, or chemical means and detoxified products can be used for feeding less-sensitive livestock, such as mature beef cattle. Most mycotoxins are heat stable in the temperature range used for food or feed processing, therefore it can be difficult to reduce mycotoxin levels significantly by thermal inactivation, while maintaining product quality. Significant reductions in mycotoxin concentrations usually occur at temperatures above 160°C (Bullerman and Bianchini, 2007). Processes such as flaking, roasting toasting and canning of grains or flour can be used to reduce mycotoxin contamination. In maize, extrusion reduced AFTs by 50%–80%, FUMs by 34%–97%, DON by over 95% and ZEA by 60%–83%, depending on the extrusion parameters (Bullerman and Bianchini, 2007). Irradiations with ionizing radiation, i.e., solar radiation, γ -radiation, and micro-waves were successful in reducing mycotoxin contamination of AFTs, OTA, FUMs, DON and ZEA in experimental trials, but the technology has not been implemented in food or feed processing, due to the high cost of irradiation units and because of a negative perception of consumers with regard to its safety (Calado *et al.*, 2014). Chemical detoxification methods could greatly reduce mycotoxin contamination, but their widespread use is limited because they not always comply with the FAO requirements. In many instances, mycotoxin degradation/transformation products have not been identified, raising questions about possible “hidden” mycotoxins which might survive the chemical process as transformed compounds with residual toxicity or that may revert to their native toxic forms after ingestion. Also, these processes may have an impact on nutritional value or palatability of feed. Internationally, the use of ammonia gas or ammonium sulfate to reduce AFTs levels in maize is widely accepted. The use of ammoniation for degradation of FB₁, DON and ZEA is more controversial. In fact, the process does not seem to reduce the toxicity of FB₁-contaminated products, in spite of the decrease in mycotoxin level, while in the cases of DON- or ZEA-detoxification, conclusive toxicity studies with decontaminated materials have not yet been conducted. Other chemical treatments have been used for mycotoxin detoxification with a certain degree of success. Ozonation is based on treatment of the products with ozone for a few seconds. Ozone is a powerful oxidizing agent that decomposes to form oxygen and is, thus, a nonpersistent and safe chemical. Ozonation has been successfully utilized for detoxification of AFTs, both in solution and in bulk maize and has also been reported to degrade trichothecenes, ZEA and OTA (Grenier *et al.*, 2014). Another strong oxidizing agent, hydrogen peroxide (H₂O₂), in combination with NaHCO₃ or Ca(OH)₂ can efficiently degrade AFTs, FUM and ZEA (Lopez-Garcia *et al.*, 1999). Other chemical treatments experimented for mycotoxin degradation include nixtamalization, (a traditional Mexican process for making tortillas and that consists of cooking corn in water and Ca(OH)₂ followed by steeping) for reduction of AFTs, FUM, ZEA and DON in maize, 0.5–2% sodium bisulfite against AFTs and DON, reducing sugars for control of FUM in maize and aqueous citric acid to degrade AFTs in feed (Grenier *et al.*, 2014).

Microorganisms have been identified that are capable of metabolizing certain mycotoxins, including AFTs, ZEA and DON, via production of extracellular lytic enzymes able to break or modify the mycotoxin molecules to non-toxic or less toxic compounds (Lyagin and Efremenko, 2019). The enzymes responsible of mycotoxin degradation may be extracted from microbial cultures and used in purified form (Loi *et al.*, 2018) for detoxification of commodities intended for feed production. The pros of this approach are the high efficiency and specificity of action of enzymes, the absence of toxicity to animals consuming the processed materials and the use, likewise all catalysts, in non-stoichiometric ratios with mycotoxins. One major con is the high cost of the enzyme purification process, which in the future might be overcome by the use of easy-to-obtain and inexpensive crude enzyme extracts (Branà *et al.*, 2020).

Dietary Interventions

Additives, known as detoxifying agents, may be added to the diet of animals (mainly of swine, poultry and cattle); these additives reduce the absorption of mycotoxins from the gastrointestinal tract and their distribution to blood, or transform the mycotoxins into less toxic metabolites. In the former case, the additives consist of materials that sequester mycotoxins by binding them on their surface (adsorption), in the latter case additives are microorganisms or microbial enzymes able to degrade or transform the mycotoxin's molecule (biotransformation). In the EU, feed additives for control of mycotoxins, defined as "substances for reduction of the contamination of feed by mycotoxins: substances that can suppress or reduce the absorption, promote the excretion of mycotoxins or modify their mode of action", have been regulated as a new functional group in the category of feed additives (EC, 2009).

Mycotoxin binders, a.k.a. sequestering agents or adsorbing agents, may be mineral, organic or synthetic materials that have the property to bind mycotoxins by stable interactions such as hydrophobic binding, hydrogen bonds, electrostatic attraction or repulsion and coordination bonds (Di Gregorio *et al.*, 2014), which do not dissociate in the gastrointestinal tract of the animal, thus limiting their bioavailability after ingestion. The complexed mycotoxin is then eliminated with the feces. The most important property of binders is the capability to remain stably complexed at the varying pH values which are encountered along the digestive tract. This property is influenced by physical properties of the binder (total charge and charge distribution, the size of the pores, and the accessible surface area) and by toxins' physicochemical properties (polarity, solubility, and shape). Among the mineral binders, the most studied are the aluminosilicates (clays), which include phyllosilicates and tectosilicates. Phyllosilicates (bentonites, montmorillonites, smectites, kaolinities, and illites) can adsorb substances on their surface or within their interlaminar space. The tectosilicates include zeolites that function like both ion-exchange material and molecular sieve since provide a large and specific binding surface but can also differentiate molecules by size, shape and charge. Hydrated sodium calcium aluminosilicate and bentonite/montmorillonites clays are the best adsorbents for AFTs, but are generally less effective in binding of ZEA, OTA, FUM and trichothecenes, with variation amongst different types of clays. Clays could adsorb micronutrients and vitamins and have negative effects on their bioavailability. Therefore, an important element for the assessment of clays suitability as binders is the adsorbent's affinity for vitamins, minerals and other nutrients. Aluminosilicate mycotoxin-binders are currently commercialized worldwide.

Natural organic binders have been studied in the prospect to integrate clays as feed additives for mitigation of major mycotoxins other than AFTs. The combination of inorganic and organic adsorbents could be useful in the most frequent cases of multi-contaminated feeds. Such sorbents include activated charcoal, micronized fibers obtained from different plant materials, yeast and fungal cell walls and components thereof, and bacterial cells. Activated charcoal has been found very effective in adsorbing different mycotoxins (including DON) in *in vitro* tests, but the results of *in vivo* trials were controversial. Generally, the adsorption properties of activated charcoal depend on the feedstock materials used for its production, surface area and pore size distribution. Activated charcoal binding is unspecific, hence essential nutrients are also sequestered, particularly if their concentrations in feed are much higher compared to those of the target mycotoxin. Micronized fibers are obtained from different plant materials such as cereals or legumes (wheat, barley, alfalfa, oat, pea hulls, dehydrated grape pomace) and consist mainly of cellulose, hemicellulose and lignin. Micronized wheat fibers exhibited beneficial effects against OTA adsorption. *In vitro*, organic sorbents have been demonstrated to be excellent in the simultaneous removal of several mycotoxins (Afb₁, ZEA, OTA and FUMs) from a liquid medium. However, cellulose materials seem to have less binding ability for Afb₁, compared to other inorganic adsorbents. Chlorophyll and its derivative chlorophyllin, which are natural constituents of green vegetables, can sequester aflatoxin in the gastrointestinal tract and impede its absorption. In addition, these compounds may have enzyme-inducing properties that contribute to mechanisms of detoxification. Interesting findings have been obtained from *in vitro* studies regarding humic acids, originating from natural decaying of organic plant materials, which have shown the capacity to adsorb mycotoxins, especially Afb₁, OTA and ZEA (Sabater-Vilar *et al.*, 2007). Biosorbents, based on yeast, fungi or bacteria cell walls are an environmentally friendly and rapidly biodegradable alternative to other sorbents. The adsorbing capability of microbial cell walls depends on the structure, especially pore shape and size, and the nature of the polysaccharides they contain. Yeast cell wall mainly consists of polysaccharides, i.e., β -D-glucan and mannans, which exhibits a great variety of accessible mycotoxin adsorption loci by different binding mechanisms (hydrogen bonds, ionic or hydrophobic interactions). *Saccharomyces cerevisiae* cell wall has proven to be able to adsorb a wide spectrum of mycotoxins, such as ZEN, OTA, FB and trichothecenes (Yiannikouris *et al.*, 2006). Recently, Haidukowski *et al.* (2019) have shown that non-viable mycelium of the edible mushroom *Pleurotus eryngii* was able to efficiently adsorb up to 85% of Afb₁ in solution, in a range of pH values from 5 to 7, mainly by a mechanism of physical adsorption. Some strains of the lactic acid bacterium *Lactobacillus rhamnosus* have the ability to bind onto their cell wall some mycotoxins in animals' small intestine. Lactobacilli adsorb more efficiently non-polar toxins, such as ZEA and Afb₁, due to hydrophobicity of their cell wall surface (Kabak *et al.*, 2006). The cell wall components involved in the process are peptidoglycans, polysaccharides and teichoic acid. *Lactobacillus rhamnosus* is regarded as a safe and functional microorganism, currently used for the production of yogurt and healthy food.

Among the synthetic adsorbents, modified aluminosilicates have been produced in order to extend the binding efficacy of natural clays, mostly restricted to AFTs, to other mycotoxins, including ZEA, OTA and FUMs. The modifications consist of alterations of surface properties by exchange of structural charge-balance cations with high molecular weight quaternary amines, which results in an increased hydrophobicity. *In vitro* testing has confirmed the improved binding capability of modified clays (Papaioannou *et al.*, 2005). Also polymeric anion exchange resins, such as cholestyramine, divinylbenzene-styrene and polyvinylpyrrolidone (a highly polar

amphoteric polymer) have been demonstrated to bind mycotoxins, in vitro and in vivo. However, so far the practical application of synthetic binders has been limited because of the high cost.

Another strategy for control of mycotoxins in animals' diet is biotransformation, that is the degradation of mycotoxins into non-toxic metabolites by mycotoxin-degrading enzymes or by microorganisms producing such enzymes (Ji *et al.*, 2016). Several microbial species, including bacteria, yeast and fungi have been recognized for their ability to biotransform mycotoxins via (de)acetylation, oxygenation, ring/side chain cleavage, de-epoxidation, isomerization or glucosylation. However, this promising strategy has found so far few practical marketable applications, due to the limited knowledge of the nature of the biotransformation by-products and their toxicity.

Mycotoxins in a Global Warming Scenario

According to the [Intergovernmental Panel on Climate Change IPCC \(2014\)](#), the Earth's climate has been going through a period of global warming since the mid-20th century, mainly due to anthropogenic greenhouse gas (carbon dioxide, methane and nitrous oxide) emissions. In the climatic change scenario drawn by IPCC, the global surface temperature is likely to rise 0.3–1.7°C in a moderate foresight, or as much as 2.6–4.8°C in an extreme foresight. The global warming will result in rising of sea levels, regional changes in distribution and levels of rainfalls, with more frequent extreme weather events such as heat waves and heavy precipitations in a number of regions. Under the extreme scenario, annual precipitation will increase at high latitudes, many mid-latitude wet regions, and the equatorial Pacific, and decrease in many mid-latitude and subtropical dry regions with likely increase in the frequency of droughts.

The growth of mycotoxigenic fungi and mycotoxin biosynthesis are affected greatly by environmental parameters, especially temperature, relative humidity and water availability. Some mycotoxigenic species might shift their geographical distribution in response to global warming, leading to changes in the pattern of mycotoxin occurrence, both qualitatively and quantitatively. In addition, some studies suggest that the elevated atmospheric carbon dioxide levels associated to the global warming may enhance fungal colonization by *Aspergillus* and *Fusarium* species and thus contribute to increased mycotoxin production in crops (Bencze *et al.*, 2017; Medina *et al.*, 2014). Climate has also major effects on plant life cycle and plant susceptibility to stresses and fungal infections, as well as on insect life cycles and attacks. Global warming and changes in rainfall amount and distribution will probably modify the onset and duration of growing seasons and the geographical distribution of certain crops. In certain world areas, crops will be likely subjected to an increased number of biotic and abiotic stress combinations, particularly to the concurrent occurrence of drought and heat stress, and increases in pest reproduction rates and damages which facilitate infection by mycotoxigenic fungi. Since almost all of the mycotoxins present in food and feeds are produced in the field, in this scenario it may be expected that the occurrence, distribution and severity of mycotoxins in several areas of the world will change and, in some cases, increase (Magan *et al.*, 2011).

Recent quantitative estimations based on predictive models have shown that increased AFB₁ and DON contamination are expected in cereals in certain regions of Europe and Africa as a result of global warming. Longer and more severe droughts are foreseen to occur in West Africa and southern Europe in the next future, which may lead to an increase in AFTs occurrence in foods and feeds. Recent unusual outbreaks of AFTs have been reported in some regions of Europe as a result of drought stress of plants that made the crops more prone to infections by *A. flavus* and biosynthesis of AFTs (Miraglia *et al.*, 2009; Battilani *et al.*, 2016). According to some prediction models, the increase of Earth temperature would result in the geographical shift of *A. flavus*, which grows well under warm and dry weather, from southern Europe to more northern and eastern regions of Europe (Van der Fels-Klerx *et al.*, 2016). This implies that AFB₁ is likely to become a consistent food safety issue for crops, particularly maize, in Eastern Europe, Balkan Peninsula and the Mediterranean regions where AFB₁ outbreaks currently occur only occasionally. Also, increased contamination of wheat grains with DON is expected as a result of climate change. Some simulations have shown an increase of up to 3 times in DON presence in wheat in north-western Europe by 2040 (Van der Fels-Klerx *et al.*, 2012). Severe rains while plants are at the flowering stage are associated with increased infection of *Fusarium* spp. to wheat heads and corn ears and may cause higher levels of mycotoxins in kernels at harvest. In maize, the production of FUM has been associated with dry weather and late season rains, which are more likely to occur under the climate change scenario. Abundant rainfalls in the proximity of harvest may also induce farmers to harvest prematurely, when grains are not completely dry, hence favoring mold contamination and mycotoxin accumulation at post-harvest.

While the studies on the possible effect of climate change on mycotoxin occurrence have been so far focused on AFB₁ and DON, it is conceivable that changes in the distribution, frequency and levels of other regulated and not regulated mycotoxins would occur similarly, which prompt for more extended analyses to evaluate the mycotoxin risk in a world climate change scenario.

Biosynthesis and Genetic Regulation of Mycotoxins

Generally, the biosynthesis of mycotoxins is a multi-step pathway involving a series of enzymatic reactions to form the final molecular structure. For most of fungal mycotoxins, the genes encoding the proteins involved in the biosynthesis process are typically located next to one another in a biosynthetic gene cluster (BGC), facilitating a coordinated regulation of their expression (Fig. 1). According to the structural classification of mycotoxins as poliketides, ribosomal and nonribosomal peptides or

Fig. 1 Schematic rendition of mycotoxin biosynthetic clusters. Lengths of genes and intergenic regions are not drawn to scale; gray blocks represent regulatory genes. (A) aflatoxin cluster in *A. flavus*; (B) trichothecene cluster in *F. graminearum*; (C) fumonisin cluster in *F. oxysporum*, *F. proliferatum* and *F. verticillioides*. A; (D) ochratoxin A cluster in *A. carbonarius*.

terpenoids, a key gene encoding for a polyketide synthase (PKS), a non-ribosomal peptidase (NRPS) or a terpene synthase, is present in the cluster. Synthases or synthetases establish the molecular backbone of mycotoxin which is then modified by a variety of tailoring enzymes such as (de)hydratases, oxygenases, hydrolases, methylases, and others to form the final complex structure. The same biosynthetic pathway may give origin to the structural diversity of mycotoxins belonging to the same mycotoxins family, as a result of the absence or the non-functioning of a gene within a biosynthetic cluster, or the variation of enzymatic activity (Hoffmeister and Keller, 2007; Keller, 2019).

Other genes encoding metabolite transport proteins and transcription factors are generally present in the mycotoxin clusters. In particular, one or occasionally more transcription factors are required to regulate the expression of the other biosynthesis genes in the cluster (Osborn, 2010; Brakhage, 2013). The most common type of cluster pathway regulators belongs to the class of C-6 zinc finger proteins that recognize palindrome motifs in cluster gene promoters. In addition to pathway-specific elements, the regulatory mechanism of mycotoxins is also composed of broad domain transcription factors and multiprotein complexes that transmit biotic and abiotic cues to biosynthesis mechanism; these regulatory processes are often interconnected and overlapping. Environmental parameters such as carbon and nitrogen sources, temperature, light, and pH, exert their influence on mycotoxin production through the mediation of global transcription factors such as CreA for carbon signaling, AreA for nitrogen signaling, and PacC for pH signaling (Brakhage, 2013). Several studies have reported both negative and positive regulation of biosynthetic genes by global regulators, turning off and on the energetically costly process of secondary metabolite production as an advantage to the producing fungus under certain environmental conditions. One of the most important multiprotein complexes of the regulatory mechanism is the Velvet complex. This heterotrimeric complex formed by VelB, VeA and LaeA, links sexual development with secondary metabolism in fungi in response to light, through a regulated spatial compartmentalization of the three proteins (Bayram *et al.*, 2008). Other regulation mechanisms could be responsible of the activation of biosynthetic genes that are based on signaling pathways or epigenetic control, the latter linked to chromatin remodeling proteins (Pfannenstiel and Keller, 2019).

The study of mycotoxin biosynthetic gene clusters is essential to gain a better comprehension of the regulatory process behind mycotoxin biosynthesis and the factors involved in mycotoxin production. Also, a thorough examination of the toxigenicity of fungal populations depending on the presence or the absence, in whole or in part, of the biosynthetic gene cluster has led to the development of successful biocontrol strategies based on the use of non-mycotoxigenic strains and is essential for the assessment of events of horizontal transmission of mycotoxin-producing capability among different populations. Finally, these studies have allowed the development of sensitive, specific, and high-throughput molecular diagnostic assays for mycotoxigenic fungi. The clusters of important mycotoxins, such as Afls, trichothecenes, FUMs and ochratoxins, have been identified, even though the characterization of some of them is to be completed. The significant advance in fungal genome sequencing and bioinformatic analyses for metabolite mining have remarkably facilitated the characterization of gene clusters involved in the biosynthetic pathway, often starting from the identification of key synthase genes.

Aflatoxins

The aflatoxin biosynthesis gene cluster is probably the most widely studied fungal secondary metabolite gene cluster and extensive studies have been conducted on the regulatory mechanisms underlying AflTs production as well.

AflTs are produced by a polyketide pathway through one of the longest and most complex processes corresponding to a coordinated enzymatic cascade and leading to the production of stable intermediate molecules such as norsoloric acid, versicolorin A, sterigmatocystin and finally, AflB₁. The aflatoxin biosynthetic gene cluster includes 30 genes within a 75-kb genomic region, and to date, at least 27 enzymatic reactions have been shown to be involved in this process, whereas the roles of several other genes belonging to the cluster, remain unclear. In addition, a 7.5 kb cluster containing a group of four genes related to the utilization of sugar is located next to the aflatoxin gene cluster (Yu *et al.*, 2000; Bhatnagar *et al.*, 2006). The gene content and organization of the cluster is highly conserved among *Aspergillus* species in section *Flavi*, which includes *A. flavus* and *A. parasiticus*. Sequence variability and deletions in various genes/regions of the aflatoxin cluster have been used to assess variability in producing species and has provided markers that can be used to monitor variation in these *Aspergillus* species and to evaluate the risk they pose when present on food commodities. In addition, understanding the genetic variability in the aflatoxin cluster is a key to the selection of safe and effective aflatoxin-nonproducing strains for biological control efforts aimed at limiting contamination in crops (Donner *et al.*, 2010).

Regulation of aflatoxin biosynthesis is controlled by pathway-specific and globally-acting regulatory factors as well as epigenetic factors. The two cluster specific regulator genes *aflR* and *aflS* (previously named as *aflI*) are adjacently located in the middle of the cluster, although they are divergently transcribed and share a 737 bp intergenic region. The *aflR* gene encodes a C-6 zinc finger transcription factor which binds to the promoter region of most of the aflatoxin structural genes, using a DNA-binding domain (Shimizu *et al.*, 2003). The AflR transcription factor acts as positive regulator by activating the transcription of genes and in turn the enzymatic process leading to the production of AflTs. Even though AflR is the main activator of the aflatoxin gene cluster, it interacts with AflS that plays the role of enhancer in the regulatory biosynthesis process (Chang, 2003). AflS does not present similarity to other proteins of known function and its exact role in aflatoxin biosynthesis is still under investigation. The *aflS* gene was shown to be regulated by AflR factor and it was also demonstrated that AflS interacts with AflR but not with the biosynthetic enzymes, revealing the co-active function of gene *aflS* in modulating the expression of aflatoxin early and mid-pathway genes in particular (Chang, 2003; Du *et al.*, 2007; Ehrlich, 2009).

Many biotic and abiotic environmental factors influence aflatoxin biosynthesis including nutritional sources; environmental effects such as water activity and temperature; physiological conditions such as pH and bioreactive agents (Yu and Keller, 2005). A complex regulation of genes guides the fungal response to environmental stimuli, affecting mycotoxin production. The activation or repression of several genes external to the aflatoxin cluster modulates aflatoxin gene expression and biosynthesis. The transcription factors CreA and AreA, which play crucial roles in the utilization of carbon and nitrogen sources, respectively, were found to be involved in the biosynthesis of AflTs (Georgianna and Payne, 2009; Caceres *et al.*, 2020). With regard to the influence of pH on the aflatoxin production, PacC seems to be the key factor involved in the related signaling pathway (Tilburn *et al.*, 1995). Globally-acting regulatory factors have been demonstrated to control the production of aflatoxins, like the Velvet complex which coordinates fungal development and secondary metabolism in a light-dependent manner (Chang *et al.*, 2012; Cary *et al.*, 2015), the global transcription factor genes *nsdC* and *nsdD* controlling both sclerotial, conidial and aflatoxin production (Cary *et al.*, 2012) as well as the recent identified global regulator Hbx1, encoding a homeobox transcription factor (Cary *et al.*, 2017). In addition, lipid metabolism especially that of fatty acid-derived oxylipins, has been shown to play a role in aflatoxin production (Tsitsigiannis and Keller, 2006). Some epigenetic mechanisms were also shown to regulate fungal development and aflatoxin production (Amare and Keller, 2014; Satterlee *et al.*, 2016).

Trichothecenes

Trichothecenes are a family of over 200 toxic sesquiterpenoids produced by species belonging to multiple fungal genera. In a recent work, Proctor *et al.* (2018) carried out a phylogenetic study on strains from nine trichothecene-producing fungal genera and reported how the diversity in trichothecene structures is largely due to gain, loss and change of function of genes during evolutionary processes. Therefore, the capability of producing trichothecene mycotoxins in certain *Fusarium* species and strains is likely the result of adaptive genetic changes, not yet clearly understood to date. All trichothecene-producing fungi examined to date have a trichothecene biosynthetic gene cluster that consists of 7–15 genes, but most of the fungi have additional trichothecene genes located in different genomic locations than cluster.

Trichothecenes are characterized by a core structure consisting of a three-ring molecule known as 12,13-epoxytrichothec- 9-ene (EPT) and then they are classified into four groups (Types A, B, C, and D) according to the substitution pattern of EPT (McCormick *et al.*, 2011). Biosynthesis of trichothecenes begins with the cyclization of farnesyl pyrophosphate, a primary metabolic intermediate, to form trichodiene through the reaction catalyzed by the terpene cyclase trichodiene synthase. Subsequently, a cytochrome P450 monooxygenase catalyzes oxygenation of trichodiene at three or four positions to yield isotrichodiol or isotrichotriol, which can cyclize non-enzymatically to form EPT or 3-hydroxy EPT (isotrichodermol), respectively. These latter molecules undergo one or more additional oxygenations, acylations and sometimes other modifications to form all trichothecene analogs. The trichodiene synthase gene (*tri5*) and the cytochrome P450 mono-oxygenase gene (*tri4*) encode the enzymes required for the essential steps that occur early in trichothecene biosynthesis (Hohn and Beremand, 1989; Kimura *et al.*, 2007).

The genetics and biochemistry of trichothecene biosynthesis have been studied most extensively in *Fusarium*. In *F. graminearum* and *F. sporotrichioides* the biosynthesis cluster includes, in addition to *tri5* and *tri4* genes, other 7 genes encoding enzymes responsible of modifications to the core EPT structure, i.e., a transporter protein (*tri12*) and the two regulatory genes *tri6* and *tri10* (Proctor *et al.*, 2018). Both species also have two smaller trichothecene loci, the first of these consists of the single gene *tri101*, while the second locus consists of the two genes *tri1* and *tri16*, which for their functional differences contribute to important structural differences of trichothecenes produced by the two species. Analysis of the *F. graminearum* genome sequence indicated that the three loci are located on different chromosomes. In other *Fusarium* species *tri1* and *tri101* are located in the main cluster (Alexander *et al.*, 2009; Proctor *et al.*, 2009). The regulatory genes *tri6* and *tri10* are predicted to encode a C-6 zinc finger transcription factor and a protein with a fungal transcription factor domain, respectively. Functional analyzes demonstrated *tri6* to be required for expression of other trichothecene genes, by binding to DNA sequence motifs in their promoter regions. The predicted TRI10 amino acid sequence does not include a DNA binding motif, anyway *tri10* gene also is required for expression of other biosynthesis genes, leading to the hypothesis that TRI10 interacts with TRI6 to induce trichothecene gene expression (Seong *et al.*, 2009). Both the *tri6* and *tri10* encoded proteins regulate the expression of most of the trichothecene biosynthesis genes and in addition of eight genes involved in the synthesis of farnesyl diphosphate, the metabolic precursor of trichothecenes and intermediate in the ergosterol and farnesol biosynthesis, thus acting as a global transcription regulators rather than pathway-specific regulators of trichothecene biosynthesis (Nasmith *et al.*, 2011).

Fumonisin

Fumonisin are structurally simple mycotoxins, but their biosynthesis requires a complex 42-kb long cluster containing 17 genes as described in *Fusarium* species. These mycotoxins consist of a linear carbon backbone with a nitrogen-containing group, one to four hydroxyl groups, and two tricarboxylate esters at various positions along the backbone. At least 28 different analogs of fumonisins were described and divided into four series designated A, B, C and P, due to the structural variation around the nitrogen atom and differences in the length of the carbon backbone (Ahangarkani *et al.*, 2014). The first described gene *fum1* is considered the key gene of this pathway, encoding a polyketide synthase which catalyzes the synthesis of the 18-carbon-long linear polyketide backbone structure. In the second step, the α -oxoamine synthase encoded by the *fum8* gene catalyzes the condensation of the polyketide with alanine to form the 20-carbon-long backbone of FB that is the most toxic member of the group, and FUMs A and P, while, during the biosynthesis of FUMs C, which is characterized by a 19-carbon-long backbone, the enzyme FUM8 catalyzes condensation of glycine to the polyketide. Several other structural genes contribute to the different structures of fumonisin analogs. As for the specific pathway regulator, the gene *fum21* is located adjacent to *fum1* and encodes a C-6 zinc finger DNA-binding transcription factor that positively regulates expression of *fum1* and *fum8*, confirming its involvement in the regulation of fumonisin synthesis. The cluster also includes the *fum19* gene encoding an ABC transporter that provides a sort of self-protection by exporting the toxin from the cell and reducing its cellular concentration (Proctor *et al.*, 2008). The order and orientations of genes within the three species *F. verticillioides*, *F. oxysporum*, and *F. proliferatum* are the same (Waalwijk *et al.*, 2004; Proctor *et al.*, 2013). However, the cluster is in a different genomic context in each species, suggesting that it has undergone translocation during the evolutionary history of fumonisin-producing *Fusaria*.

In species of *Aspergillus* section *Nigri* the composition of the fumonisin cluster is different than in *Fusarium* species and only presents 11 genes including the transcription factor *fum21*, which was found to regulate most of the cluster genes. The *A. niger* fumonisin cluster lacks the homolog of gene *fum2*, which is responsible for the final hydroxylation in the formation of FUM B₂ in *Fusarium*. Therefore, these *Aspergillus* species are only able to produce FUM B₂, B₄, and B₆, but not the most toxic one, FB₁ (Gil-Serna *et al.*, 2020). It was suggested that the fumonisin cluster in *Aspergillus* species was acquired via horizontal gene transfer from a common ancestor, by removing and/or reshuffling the genes (Khaldi and Wolfe, 2011; Aerts *et al.*, 2018).

Ochratoxins

The biosynthesis pathway of OTA has been largely clarified in recent years, essentially due to the great increasing of genome sequencing projects which led to identify the OTA clusters in several producing species belonging to *Aspergillus* and *Penicillium* genera. The key genes present in the biosynthesis cluster have been characterized and the study of their roles has resulted in a hypothesis about the biosynthesis mechanism and about the sequence of reactions along the pathway (Geisen *et al.*, 2006; Gallo *et al.*, 2012, 2017). OTA is a hybrid chlorinated molecule composed of a polyketide dihydroisocoumarin moiety which, according to this hypothesis, is firstly linked via amide bond to the amino acid phenylalanine to form ochratoxin B that then undergoes an halogenation reaction to add the chlorine atom to the molecule; the compound ochratoxin α may occur as a product of hydrolysis of OTA.

In the biosynthesis cluster, the OTA *pks* gene encodes the polyketide synthase required in the first step of the pathway, which is the formation of the isocoumarin pentaketide group from acetate and malonate. Adjacent to the *pks* gene, there is the OTA *nmps* gene encoding the peptide synthetase essential for the link between the dihydroisocoumarin and the phenylalanine synthesized via the shikimic acid pathway. In addition to the halogenase gene encoding the protein responsible of the introduction of the chlorine atom in the structure of OTA, two other genes are located in the cluster. They encode a P450 oxidase and a bZIP transcription factor that have been demonstrated to be involved in the pathway (Wang *et al.*, 2018). Other genes were annotated in OTA biosynthesis clusters of several producing species, such as a predicted transporter protein and one or two other fungal specific

transcription factors, whose role in the biosynthetic pathway needs to be investigated further. Therefore, length and composition of the OTA cluster remain not yet completely defined.

Also, the hypothesis of a possible involvement of two PKS proteins in the biosynthesis of OTA has been proposed, due to the identification of two putative OTA-related gene clusters, each of them containing a PKS gene, in *A. westerdijkiae* and *A. ochraceus*. Gene inactivation and expression studies suggested that one PKS is directly involved in biosynthesis of OTA while the other PKS might complement the expression of the former gene and be involved in the biosynthesis indirectly (Wang *et al.*, 2015; Han *et al.*, 2016).

At present, most of the regulatory aspects underlying the production of OTA remain unclear. It is likely that some of them are based on functioning models already identified for the production of other mycotoxins. The bZIP transcription factor positioned in the cluster probably acts as a pathway-specific regulator that controls production of OTA by regulating the other biosynthetic genes, but still its action mechanism remains undetermined. An additional transcription factor located adjacent to the biosynthetic genes is a zinc finger DNA-binding protein and was proved also to regulate the expression of some of the biosynthesis genes, although its inactivation merely reduces production of OTA (Wang *et al.*, 2018). Among the global regulators, the heterotrimeric Velvet complex has been the most studied in OTA producing fungi to clarify the link of the light-dependent fungal morphology and sexual development to production of OTA (Crespo-Sempere *et al.*, 2013). Moreover, the correlation between a NaCl rich environment and biosynthesis of OTA by *Penicillium* producing species was demonstrated by Schmidt-Heydt *et al.* (2012) to be mediated by the HOG MAP kinase signal cascade pathway under the hypothesis that the excretion of OTA carrying a chlorine in its molecule, contributes to the adaptation to salt rich environment by ensuring chloride homeostasis in the cell.

RNA Interference in Fungi

Alessandro Silvestri and Luisa Lanfranco, University of Turin, Turin, Italy

The Discovery of RNA Interference

RNA interference (RNAi) is a biological process, almost universally presents in eukaryotes, involved in the repression of gene expression (gene silencing) at transcription and/or post-transcription levels. In this process, specific RNA or DNA target molecules are recognized by short non-coding RNA molecules (20–30 nucleotides), known as small RNAs (sRNAs), and silenced by a multiple protein complex.

The first reported observations of RNAi date back to the early 1990s when two independent research groups, that were working on the over-expression of genes involved in pigment production in a plant (Napoli *et al.*, 1990) and a fungus (Romano and Macino, 1992), obtained unexpected results. In particular, they observed that a number of transformants, instead of being characterized by a more intense pigmentation, showed albino or variegated phenotypes. The peculiar feature was that those phenotypes were often transient and not always transmitted to the progeny; they called this phenomenon as “co-suppression” and “quelling”, respectively. The molecular basis of this mechanism remained unclear until 1998 when Fire and colleagues understood that the nature of the silencing trigger was double-stranded RNA (dsRNA, Fire *et al.*, 1998). Their work brilliantly highlighted that, in nematodes, dsRNAs activate the sequence-specific silencing of endogenous genes, producing a much stronger effect compared to sense or antisense sequence-specific single-stranded RNAs (Fire *et al.*, 1998). During the following years, the molecular details of RNAi were elucidated giving rise to a number of biotechnological applications, from medicine to agriculture. For the impact of this discovery, in 2006 Fire and Mello were awarded the Nobel Prize in Physiology or Medicine.

The Core of RNAi Machinery: DCL, AGO and RdRp

In a simplified model valid for almost all eukaryotes, the general RNAi pathway can be described as a process involving three classes of proteins (Fig. 1): Dicer (or Dicer-like; DCL), Argonaute (AGO) and RNA-dependent RNA polymerase (RdRp; Ipsaro and Joshua-Tor, 2015).

DCL are enzymes that process dsRNAs or single-stranded hairpin RNAs into small RNA (sRNA) duplexes, typically 21–25 nucleotide(nt)-long (Bernstein *et al.*, 2001). The cleavage activity of DCL is provided by a pair of Ribonuclease III (RNase III) domains which act, together with a PAZ domain (primarily responsible for the recognition of the dsRNAs to be cleaved), as a molecular ruler to produce sRNA duplexes of the appropriate size, characterized by 2-nt overhangs at the 3'-ends and by a monophosphate group at the 5'-ends (MacRae and Doudna, 2007; Zhang *et al.*, 2004). The sRNA duplexes are then loaded onto AGO, the silencing effector proteins, which retain only one sRNA strand to become the minimal constituents of the (1) RNA-induced silencing complex (RISC; Cenik and Zamore, 2011), involved in post-transcriptional gene silencing (PTGS), or the (2) RNA-induced transcriptional silencing complex (RITS; Moazed, 2009), a nuclear form of RISC involved in transcriptional gene silencing (TGS). The sRNAs let the RISC or RITS to recognize, by sequence complementarity, their target nucleic acid molecules (RNA or DNA, respectively) that can therefore be silenced in different ways: (1) through mRNA cleavage or destabilization, or translation inhibition (Ipsaro and Joshua-Tor, 2015; Verdel *et al.*, 2004); or (2) through histone and/or RNA-directed DNA methylation (Moazed, 2009; Fig. 1).

AGO have a bilobal structure: one lobe is composed by a PAZ (the same found in DCL) and a N-terminal domains, the other by a MID and a PIWI domains (Kuhn and Joshua-Tor, 2013). The PAZ/N-terminal lobe recognizes the DCL-derived sRNA duplexes, thanks to their typical 2-nt 3'-overhangs, and binds only one strand of the sRNA duplex (the sRNA guide) at its 3'-end, discarding the other one. The second lobe, MID, is responsible for securing the sRNA guide to the protein by the aspecific binding of its 5' monophosphate, while the PIWI domain, which possesses an RNase-H fold, provides the RISC complex with the endonuclease catalytic effect directed against the target transcripts. Three paralogous classes of AGO are present in eukaryotes: the widespread AGO-like, the Piwi-like (only found in animals) and the *Caenorhabditis elegans*-specific group 3 AGO (Hutvagner and Simard, 2008; Wilson and Doudna, 2013). AGO are considered as the minimal and necessary determinant of RNAi; indeed, unlike DCL and RdRp, no AGO-independent RNAi pathways have been described so far (Ipsaro and Joshua-Tor, 2015).

The third class of proteins, the RdRp, is responsible for the “cascade effect”: a fundamental property of RNAi through which a weak initial silencing signal can be drastically amplified in a positive feedback process (Baulcombe, 2015). In this way, few silencing RNA molecules can produce a massive silencing response, resulting sometimes in a huge reprogramming of the cell transcriptome. RdRp are commonly present in fungi and plants but absent, with the exception of nematodes, in the majority of animals. The RdRp-mediated silencing amplification can be accomplished in different ways: (1) RdRp can interact with AGO-cleaved mRNAs to synthesize their antisense fragments (in a sRNA primer-independent or -dependent manner), producing dsRNAs that are then recruited in the DCL circuit; or (2) they can directly produce sRNAs using an mRNA as a template. In plants RdRp are fundamental for defense against viral infections (Childiyal and Zamore, 2009). In addition to the amplification of

Fig. 1 Simplified model of the RNAi pathway. DCL (Dicer-like) enzymes process dsRNAs or single-stranded hairpin RNAs with different origins into small RNA (sRNA) duplexes. Only one sRNA strand (indicated in red) is then loaded onto AGO (Argonaute), the silencing effector proteins, to become the minimal constituents of the RNA-induced silencing complex (RISC) involved in post-transcriptional gene silencing (PTGS) which triggers the cleavage or the translation inhibition of target transcripts (right). AGO can be part of the RNA-induced transcriptional silencing complex (RITS) involved in transcriptional gene silencing (TGS) through DNA methylation and histone modifications of specific target DNA sequences (left). RdRp (RNA-dependent RNA polymerases) are responsible for the production of dsRNAs by the synthesis of antisense fragments from AGO-cleaved transcripts (amplification of silencing signal) or from non-degraded mRNA (*de novo* dsRNA production). Some classes of RdRp show a dual DNA/RNA-dependent RNA polymerase activity: they can recognize repetitive DNA elements (typical of transposable elements), synthesize ssRNA molecules and turn them into dsRNAs.

silencing signals, the RdRp may play a major role also in the activation of RNAi pathway by producing *de novo* dsRNAs from non-cleaved single-stranded (ss) RNA precursors but also, in fungi, in producing ssRNA precursors from DNA templates (Calo *et al.*, 2012; Lee *et al.*, 2010a).

In the simplified model proposed above, several accessory molecular components have been (intentionally) omitted. At molecular level, all these components cooperate to produce a complex and variegated system that can be differentiated, following a reductionist perspective, in a number of RNAi sub-pathways (Childiyal and Zamore, 2009).

Different Classes of sRNAs are Involved in RNAi

Small RNAs are the informational components of RNAi, directing its activity in a sequence-specific manner. Different classes of sRNAs have been proposed based on the proteins responsible for their biogenesis, on the RNAi pathway in which they are inserted, on their binding affinity with specific AGO proteins, on the species in which they have been discovered or on the biological functions they carry out (Childiyal and Zamore, 2009). However, because of the intrinsic variegated nature of RNAi, a classification system valid for the whole eukaryotic kingdom is missing. Historically, sRNAs have been divided in three major groups: (1) small-interfering RNAs (siRNAs), which include sRNAs deriving from dsRNA precursors, found in almost all RNAi-competent organisms; (2) microRNAs (miRNAs), which include those sRNAs precisely excised from ssRNA molecules with an intra-molecular self-complementary (hairpin) structure, typical of plants and animals; (3) PIWI (P-element-induced wimpy testes)-interacting siRNAs (piRNAs), which derive from ssRNA precursors to be loaded onto the Piwi-like AGO, specific of animals (Childiyal and Zamore, 2009).

miRNAs, siRNAs and piRNAs are regulated in vivo by specific modifications (Borges and Martienssen, 2015). Among them, two of the best characterized are the uridylation and the 2'-O-methylation of the 3'-ends of sRNAs, which have two opposite molecular meanings (Kim *et al.*, 2010). In plants, the 2'-O-methylation of sRNAs, which is carried out by the enzyme HEN1, is associated with sequence stability: indeed, the methylation prevents sRNAs from being uridylated by HESO1 and, consequently, from being degraded by SDN1 (Borges and Martienssen, 2015). For this reason, functional sRNAs are generally methylated during their biogenesis. HESO1 is associated with the RISC complex where it promotes (and this seems to be its primary function) the uridylation, and thus degradation, of the 3'-ends of the 5' fragment of the AGO-cleaved mRNAs (Ren *et al.*, 2014). In this context, the 2'-O-methylation is necessary to avoid the unintentional uridylation by HESO1 of the AGO-loaded sRNA guide that would lead, after its degradation, to a loss of silencing information.

In plants a robust hierarchical classification system for sRNAs, based on their biogenesis, has been proposed (Axtell, 2013). Contrary to plants, in fungi sRNAs are mainly classified following the nomenclature of the specific RNAi pathway in which they have been first described. In the following sections, some specificities of the fungal RNAi and sRNA world will be discussed.

An Overview on RNAi and sRNAs in Fungi

RNAi is a widespread mechanism within the fungal kingdom, almost all fungal lineages possess the key components of RNAi machinery (reviewed in Nicolás and Garre, 2017; Torres-Martínez and Ruiz-Vázquez, 2017). Fungi often possess more than one gene encoding for the basic components of RNAi machinery, typically 1–2 DCL, 1–4 AGO and 1–4 RdRp (Chang *et al.*, 2012). A remarkable exception to this general rule is represented by the arbuscular mycorrhizal fungi (subphylum Glomeromycotina) which are characterized, with up to 40 genes depending on the species, by the expansion of AGO family (Lee *et al.*, 2018; Silvestri *et al.*, 2020, 2019).

The molecular details of fungal RNAi have extensively studied in few model species, in particular in the Ascomycetes *Neurospora crassa* (Dang *et al.*, 2014) and *Schizosaccharomyces pombe* (Martienssen and Moazed, 2015) and in the Mucoromycetes *Mucor circinelloides* (Torres-Martínez and Ruiz-Vázquez, 2016). In these three examples, different - or partially different - RNAi pathways involved in different biological functions have been discovered. The emerging picture seems to suggest that RNAi in fungi is, more than in plants, a highly variegated mechanism that even includes a number of species-specific sub-pathways. These fungal RNAi pathways can be divided, based on the biological function they perform, in two groups: (1) defense-related pathways and (2) endogenous regulatory RNAi pathways.

Defense-related RNAi Pathways

All living systems have to cope with a number of threats that can compromise their survival. Among them, specific genetic elements, such as viruses, transgenes/plasmids or (retro-)transposons, are generally dangerous for host organisms since their replication activity, if not actively thwarted, can be detrimental to cell homeostasis or genome integrity. In this context, RNAi plays a major role in cell defense by suppressing viral replication and the potential genome-damaging genetic elements. In fungi different defense-related RNAi pathways have been identified, some active during vegetative growth, others during sexual reproduction (reviewed in Chang *et al.*, 2012; Nicolás and Garre, 2017; Torres-Martínez and Ruiz-Vázquez, 2017).

Defense against mobile elements and transgenes

One of the very first characterized RNAi pathway was the “quelling” phenomenon in *N. crassa* (Romano and Macino, 1992). Quelling is a PTGS pathway active during vegetative growth that is involved in genome defense through the suppression of

transposon activity (Fulci and Macino, 2007). This pathway relies, considering only the three components of RNAi machinery presented above, on a peculiar DNA/RNA-dependent RNA polymerase (named QDE-1; Lee *et al.*, 2010a), on two functionally redundant DCL (DCL-1 and DCL-2; Catalanotto *et al.*, 2004) and an AGO (QDE-2; Cogoni and Macino, 1997). In quelling, QDE-1 is responsible for the initial triggering of RNAi pathway; indeed, it cooperates with other components, such as a RecQ DNA helicase (QDE-3) and a replication protein A (RPA), to recognize DNA tandem repeats - typical of transposable elements or multiple transgene copies - and to produce aberrant RNAs through its DNA-dependent RNA polymerase function. These molecules are then turned into dsRNAs by the same QDE-1, processed by DCL-1/2 into 25-nt long siRNAs and finally loaded onto QDE-2 for the PTGS of RNA target sequences corresponding to the original DNA tandem repeats.

In *N. crassa* another RNAi process, known as qiRNA (QDE-2-interacting small RNA) pathway, is involved in genome defense during the vegetative growth (Lee *et al.*, 2009). This system is mechanistically similar to quelling but it differs from the latter mainly because it gives rise to specific sRNAs (qiRNAs) only from the repetitive ribosomal DNA clusters. qiRNAs are produced as a specific response to dsDNA breaks and likely act as inhibitors of protein translation to protect the cell until the DNA damage is repaired.

Both these RNAi pathways are dependent on homologous recombination (HR) for their activation, with the difference that the qiRNA also needs a dsDNA break. In fact, contrary to what happens to other repetitive genomic regions, in the absence of DNA damage the ribosomal DNA clusters are generally protected from HR in order to prevent a potential detrimental loss of rDNA copy (Dang *et al.*, 2014).

Besides the case of *N. crassa*, quelling-like pathways have been identified and characterized in a number of other fungi, such as *M. circinelloides*, *Trichoderma atroviride*, *Fusarium graminearum*, *Aspergillus nidulans*, *Cryptococcus neoformans* and *Magnaporthe oryzae* (Torres-Martínez and Ruiz-Vázquez, 2017 and references therein). In all these examples the RNAi components cooperate to defend the cell against transposons, retrotransposons and transgenes, in processes molecularly similar to the *N. crassa* quelling. However, a remarkable exception to the all the systems listed above is the quelling-like mechanism of *M. circinelloides* in where, as a unique case so far described in the fungal kingdom, amplification of silencing signals has been documented (Calo *et al.*, 2012). In this organism, two non-redundant RdRp are active in the PTGS pathway: the first is required for RNAi initiation (RdRP-1; similarly to QDE-1) while the second (RdRP-2) for silencing amplification. RdRP-2 recognizes the targeted mRNA sequences and, using them as templates, synthesizes dsRNA molecules that give rise to new siRNAs (known as secondary siRNAs) through the DCL circuit.

In addition to the previous pathways, *N. crassa* is also characterized by a further PTGS RNAi process, active during sexual reproduction, that is known as meiotic silencing by unpaired DNA (MSUD; Shiu *et al.*, 2006, 2001). MSUD participates to the protection of genome integrity by recognizing and silencing, during meiosis, the unpaired sequences present only in one parental chromosome (likely mobile elements). In this pathway, a number of proteins initially cooperates to produce aRNAs from the unpaired sequences which are then subsequently converted into dsRNAs by the RdRp SAD-1 and into MSUD-associated siRNAs (masiRNAs; 25-nt long and enriched in uracil at their 5' end) by DCL-1. The AGO protein SMS-2 is finally involved in the silencing of target sequences. In the Basidiomycetes *C. neoformans*, a different RNAi pathway for defense against transposons during sexual reproduction, named sex-induced silencing (SIS), has been reported (Wang *et al.*, 2010).

For as regards the TGS pathway, the only example so far reported in fungi is the heterochromatin formation in *Schizosaccharomyces pombe* (Martienssen and Moazed, 2015; Verdel *et al.*, 2004). Heterochromatin is a condensed form of chromatin, fundamental for genome stability in eukaryotes. Heterochromatin ensures transcriptional suppression and is associated to those genomic regions characterized by highly repetitive elements, typically originated from the replicative activity of transposable elements. In the *S. pombe* heterochromatin formation pathway, nascent transcripts from non-coding genomic regions are turned into dsRNA by the unique RdRp and processed into siRNAs by the DCL. These siRNAs, after being loaded onto the single AGO, allow the recognition of the original DNA repeat regions. AGO-siRNA duplexes are included into RITS that is responsible, together with other recruited molecular components, of specific histone modifications (mainly methylation of histone H3 at the arginine position 9). This leads to the heterochromatin formation and thus to inhibition of transcriptional activity; in this way, the potential transposon detrimental action is suppressed.

Defense against viruses

One of the first functions assigned to RNAi was the defense against viral infections (Nicolás *et al.*, 2013). Fungi from all phyla are indeed infected by viruses (Herrero *et al.*, 2009). Fungal viruses (mycoviruses) are, in most cases, RNA entities encoding for at least one RdRp that is necessary for their replication (Ghabrial *et al.*, 2015). Mycoviral infections are generally asymptomatic (Roossinck, 2011) even if sometimes they can give rise to peculiar phenotypes, such as the case of *Cryphonectria parasitica*, the phytopathogenic agent of the chestnut blight. When infected by viruses of the genus *Hypovirus*, *C. parasitica* shows a reduced virulence (Milgroom and Cortesi, 2004). It is common for fungal endophytes of plants to host mycoviruses, which can sometimes play beneficial roles (Bao and Roossinck, 2013). An emblematic example is the tripartite mutualistic interaction between a plant, an endophytic fungus and its mycovirus, where the mycovirus was shown to be necessary to confer heat tolerance to the whole biological system (Márquez *et al.*, 2007).

The replication of almost all mycoviruses is characterized by a dsRNA intermediate; thus, during this phase, host DCL can process the sequences into viral sRNAs able to target the viral genome. A proof that fungal RNAi provides antiviral defense arises from the amount of new mycoviral genomes that have been discovered in the last years by exploiting small RNA-seq data (e.g., Nerva *et al.*, 2016). Nevertheless, the sRNA-seq approach is sometimes not sufficient to reconstruct *in silico* the whole genome sequence of mycoviruses, suggesting that some species can escape the host RNAi pathway (Nerva *et al.*, 2018). Anyway, direct

evidence of antiviral activity for fungal RNAi has been collected. This is the case of *C. parasitica* infected by *Cryphonectria hypovirus 1* (Segers *et al.*, 2007), *A. nidulans* infected by different viruses (Hammond *et al.*, 2008) and *Colletotrichum higginsianum* infected by *Colletotrichum higginsianum nonsegmented dsRNA virus 1* (Campo *et al.*, 2016). In analogy to viruses infecting non-fungal hosts, some mycoviruses have developed strategies to suppress the fungal anti-viral RNAi pathway (Hammond *et al.*, 2008; Segers *et al.*, 2006; Yaegashi *et al.*, 2013); this is a further indication that fungal RNAi serves as an antiviral defense system.

Endogenous Regulatory RNAi Pathways

In addition to defense against viruses, transgenes and mobile elements, which can be considered as exogenous genetic elements, RNAi plays a major role in eukaryotes also in the regulation of endogenous gene expression. However, in fungi the endogenous regulatory role of RNAi has been less widely studied compared to other organisms, such as plants or animals, mainly because fungal RNAi knock-out mutants often lack evident physiological or developmental phenotypes (Nicolás and Garre, 2017; Torres-Martínez and Ruiz-Vázquez, 2017). Most of the knowledge arises from studies conducted on *N. crassa* and *M. circinelloides*; in these two examples, different reverse genetics approaches, leading to the suppression of specific components of RNAi machinery, have allowed the identification of several classes of endogenous regulatory sRNAs and sRNA-generating processes.

A first group of fungal endogenous regulatory sRNAs is the class of miRNA-like identified in *N. crassa* (Lee *et al.*, 2010b). These miRNA-like share several features with plant miRNAs: they indeed originate through the precise excision of a sRNA fragment from an hairpin RNA precursor that is previously transcribed from a non-coding region. *N. crassa* miRNA-like are generally 25-nt long and enriched in uracil at their 5'-ends. Even if direct proof of their role in the regulation of gene expression is still lacking, the collected evidence supports this hypothesis; indeed, RNAi mutants show higher expression of the miRNA-like predicted target genes. Direct and indirect evidence of miRNA-like has also been collected in other Ascomycota and Basidiomycota species (Villalobos-Escobedo *et al.*, 2016) and, concerning basal fungi, in Glomeromycotina (Silvestri *et al.*, 2020, 2019).

A second group of endogenous sRNAs are the exon-derived siRNAs (*ex-siRNAs*) of *M. circinelloides* (reviewed in Torres-Martínez and Ruiz-Vázquez, 2016). The *ex-siRNAs*, that can be divided in 4 classes, originate from mature mRNAs in a DCL-dependent way. Class 1 and 2 *ex-siRNAs* are generally 23–24 nt-long sequences, are enriched in uracil at their 5'-ends and do not show a strand bias (they are both sense and anti-sense to the parental mRNA). These sRNAs are involved in the suppression of gene expression of the transcripts from which they originate. Class 3 and 4 *ex-siRNAs* are instead not characterized by specific length in nucleotide, are mostly sense to the originating exons and are not enriched in uracil at their 5'-ends; despite they are DCL-dependent, all these features suggest that they play a role in a non-canonical RNAi pathway.

M. circinelloides is also characterized by another group of gene regulator sRNAs, named rdRNAs, that are produced in a DCL-independent but RdRp-dependent way (reviewed in Torres-Martínez and Ruiz-Vázquez, 2016). These sRNAs share some features with class 3 *ex-siRNAs*: indeed they are almost all sense to mRNAs, show a random size distribution in terms of nucleotides and are not enriched in uracil at their 5'-ends but at the penultimate position of their 3'-ends. For these reasons, rdRNAs seem to derive from non-random degradation of mRNAs and likely share a partially similar biogenesis pathway with class 3 *ex-siRNAs*. Interestingly, a new class of RNase III protein (R3B2) displaying unusual domain organization is involved in the biogenesis of rdRNAs. R3B2 have been only found in Mucorales and, for their similarity with RNase III domains of bacteria belonging to Burkholderiales, they are probably a product of horizontal gene transfer event occurred between bacteria and a Mucorales ancestor (Trieu *et al.*, 2015).

Other classes of fungal sRNAs include the natural antisense transcript siRNAs (*nat-siRNAs*; Donaldson and Saville, 2012), that derive from the RNAi processing of dsRNAs formed by the overlapping of sense and antisense transcripts, and the *N. crassa* dicer-independent siRNAs (*disiRNAs*; Dang *et al.*, 2013) that, originating from gene-rich regions, they induce a specific type of transcription-dependent DNA methylation.

Loss of RNAi in Some Fungi

Even if the large majority of eukaryotes possess RNAi, there are some specific cases in which the evolution has led to the loss of key RNAi genes. In fungal kingdom, one of the best characterized example concerns the model yeast *Saccharomyces cerevisiae*, for which the loss of RNAi genes has been associated with the consistent infection with vertically transmitted dsRNA viruses (Drinnenberg *et al.*, 2011). Indeed, these viral entities, known as “killer viruses”, encode for toxic proteins that, after being secreted into the yeast growth medium, are able to kill nearby virus-free cells but not the virus-infected ones, therefore providing a net selective advantage for the latter. However, the stable infection with killer viruses is incompatible with an active RNAi suppressing viral gene expression. Under these specific circumstances, it is plausible that the original *S. cerevisiae* ancestors who lost the RNAi competency were positively selected during evolution, as the killer phenotype more than offsets the disadvantage of lacking RNAi. Similar selective pressures have led to the loss of RNAi, as independent events, also in other phylogenetically distant species, such as the basidiomycete *Ustilago maydis* (Drinnenberg *et al.*, 2011).

Besides the killer phenotype, the lack of RNAi in other species is sometimes related to different benefits, as it has been observed for the animal pathogen *Cryptococcus deuterogattii* (Nicolás and Garre, 2017). This fungus has a strictly parasitic lifestyle and, for this reason, it needs to continuously evolve in order to escape the host defense. In this case, the lack of an active RNAi has been

Fig. 2 Fungal sRNAs can act as pathogen effectors. Plants recognize the presence of fungal pathogens and activate the defense responses (left). Some fungal species can secrete sRNAs into the plant host cells, such as the case of transposon-derived *B. cinerea* sRNAs (Wang *et al.*, 2017; Weiberg *et al.*, 2013), silencing the host defense-related genes (right). These fungal sRNAs act as pathogen effectors by binding the plant AGO proteins. Adapted from Baulcombe, D., 2013. Small RNA – The secret of noble rot. *Science* 342, 45 with permission.

associated to the evolutionary advantage of having an increased genome mutation rate (due to the uncontrolled retrotransposons replication activity) and, consequently, a higher genetic variability that can be exploited by the pathogen as a counter-defense strategy (Feretzaki *et al.*, 2016).

The Role of sRNAs and RNAi in Inter-kingdom Interactions

In recent years it has been discovered that sRNAs play a role, beside endogenous gene regulation and genome protection, also in interspecies communication, in a process known as cross-kingdom RNAi (reviewed in Chaloner *et al.*, 2016; Huang *et al.*, 2019). Cross-kingdom RNAi was firstly observed in the pathogenic interaction between *Arabidopsis thaliana* and the necrotrophic fungus *Botrytis cinerea* (Weiberg *et al.*, 2013). In this work, the authors brilliantly demonstrated that, during infection, some 21–22 nt-long *B. cinerea* sRNAs, produced in a DCL-dependent way from long-terminal repeat retrotransposons, are transferred into the host cells (Fig. 2). Once in the plant cells, the fungal sRNAs are loaded onto plant AGO1 which silences, in a PTGS manner, specific defense-related genes, such as mitogen activated protein kinases (MAPKs), cell-wall-associated kinases, and genes involved in the accumulation of reactive oxygen species (ROS); in other words, the pathogen “hijacks” the host RNAi system at its own advantage.

Since this first discovery, cross-kingdom RNAi has been reported in several other pathogenic/parasitic interactions, in which sRNAs can behave both as “attack” and as “defense” molecules (i.e., can be transferred from the pathogen/parasite to the host or vice versa). For examples the fungal pathogens *Verticillium dahliae* (Wang *et al.*, 2016) and *Puccinia striiformis* f. sp. *tritici* (Wang *et al.*, 2017) and the parasitic plant *Cuscuta campestris* (Shahid *et al.*, 2018) exploit cross-kingdom RNAi to attack their host plants. On the other hand, plants can defend themselves by delivering sRNAs that target virulence genes in the pathogens, as it has been observed in plant interactions involving the fungi *V. dahliae* (Zhang *et al.*, 2016), *B. cinerea* (Cai *et al.*, 2018) or *Fusarium graminearum* (Zhang *et al.*, 2016; Jiao and Peng, 2018; Zhang *et al.*, 2016) or the oomycete *Phytophthora capsici* (Hou *et al.*, 2019).

The occurrence of cross-kingdom RNAi-like mechanisms is not limited to plants. The movement of sRNAs able to interfere with host gene expression has been also reported in the interactions between gastrointestinal nematodes (Buck *et al.*, 2014; Chow *et al.*, 2019) and mammals and between endobacteria (genus *Wolbachia*; Mayoral *et al.*, 2014) or the fungal pathogen *Beauveria bassiana* (Cui *et al.*, 2019) and insects. Furthermore, it has been shown that mobile sRNAs can also regulate gene expression in organism not provided with a functional RNAi machinery, such as the case of the movement of sRNAs from human cells to the malaria agent *Plasmodium falciparum* (Lamonte *et al.*, 2012) or gut bacteria (Liu *et al.*, 2016). Interestingly, gut microbiome is also influenced by dietary-derived plant sRNAs (Teng *et al.*, 2018). Recently, for the first time it has been demonstrated the involvement of cross-kingdom RNAi also in mutualistic interactions (Ren *et al.*, 2019), as bacteria of genus *Bradyrhizobium* secrete transfer RNA-derived sRNAs into cells of the host legume plant; these sRNAs, by binding plant AGO1, regulate the expression of nodulation-related host genes.

In 2018, Cai *et al.* (2018) clarified the mechanism through which plants send sRNAs into interacting fungi. In this work, it was shown that, at the *Arabidopsis*-*B. cinerea* contact interface, specific plant exosomes containing sRNAs are secreted into the apoplastic space and are then taken up by fungal cells. The plant knock-out mutants impaired in the production of exosomes were no longer able to defend themselves from the pathogen by means of sRNAs. Similarly, this exosome-mediated transfer mechanism has been reported also in a plant-oomycete interaction (Hou *et al.*, 2019) and in animal systems (Buck *et al.*, 2014; Chow *et al.*, 2019). In particular, the latter discovered that the nematode *Heligmosomoides baker* uses extracellular vesicles (EVs) to deliver, into the host cells, sRNAs together with AGO proteins; in this way, it is possible that few transferred sRNA molecules can have a very efficient

effect in the recipient organism since it is known that AGO-sRNA complexes can be stable for more than 3 weeks and, during this time, can maintain their silencing competency (Smibert *et al.*, 2013).

Cross-kingdom RNAi can also be artificially induced through the expression of RNAi constructs directed against interacting organisms. These techniques are known as host-induced (HIGS) or viral-induced (VIGS) gene silencing (reviewed in Baulcombe, 2015). Both approaches are powerful tools to protect plants from pathogens/parasites/insect pests but are also great technical opportunities for basic research, to obtain gene silencing in non-genetically transformable obligate plant biotrophs, such as arbuscular mycorrhizal fungi (Helber *et al.*, 2011; Kikuchi *et al.*, 2016; Tsuzuki *et al.*, 2016; Voß *et al.*, 2018; Xie *et al.*, 2016).

In addition to HIGS and VIGS, a further RNAi-based approach to control plant pathogens has been proposed: the spray-induced gene silencing (SIGS). In this case, it has been observed that the simple exogenous delivery onto crops of sRNAs/dsRNAs targeting fungal genes is sufficient to protect plants from pathogens (Koch *et al.*, 2016; McLoughlin *et al.*, 2018; Wang *et al.*, 2016). SIGS appears as a promising technique that could be likely used in agriculture in the next future (Huang *et al.*, 2019).

All these findings suggest that exchange of sRNAs between interacting organisms and cross-kingdom RNAi-like processes are likely extremely widespread natural communication strategies.

All living organisms, from the simplest to the more complex, respond to external environmental changes through adaptive mechanisms. These mechanisms acquire special relevance in those microbes whose perpetuation depends on the establishment of an intimate relation with a host and that leads to a tight regulation of microbial genes that promote growth and survival (Biswas *et al.*, 2007; Cottier and Muhlschlegel, 2009; Alonso-Monge *et al.*, 2009b). Signal transduction cascades are essential molecular mechanisms that mediate this adaptation, and those involving mitogen activated protein kinases (MAPKs) are very relevant among eukaryotes. In fungi, they were first described in the *Saccharomyces cerevisiae* mating pathway, but gradually identified and characterized in many other fungi. In the case of pathogenic fungi, these signaling pathways play a key role in the adaptation of the microorganisms to the host environment and for the development of disease. This topic has been largely investigated in one of the main pathogenic yeasts, *Candida albicans* and, for this reason, it will be the main focus of the present chapter.

C. albicans is a pathogenic fungus of special significance to humans. Its first descriptions date from the first half of the 19th century, where several physicians described the presence of fungus in newborns oral thrush. *C. albicans* is frequently isolated in nosocomial blood-borne infections and is responsible for a wide range of diseases, collectively called candidiasis, which arise as a consequence of the inability of the host immune response to control fungal proliferation. This microorganism does not have a significant life cycle outside the host, and it is a frequent colonizer of humans, inhabiting the mucosa and especially the gastrointestinal and genitourinary tract of 30–70% of healthy individuals. *C. albicans* therefore behaves as an opportunistic pathogen, accounting for approximately 400,000 life-threatening infections per year (with a mortality rate exceeding 30%) and a far greater number of mucosal infections (Brown *et al.*, 2012). Clinical manifestations associated with candidiasis range from superficial (and relatively easy to handle through drug therapy) to mucosal and/or deep infections (oropharyngeal, vulvovaginal and invasive candidiasis) that may be of extreme severity among compromised individuals.

Despite the existence of some effective antifungals (polyenes, azoles and echinocandins), they all suffer problems related to cost, toxicity, pharmacokinetics or emergence of resistance (Kontoyiannis and Lewis, 2002; Akins, 2005) that severely limit its usefulness or may do it in a future. In addition, the eukaryotic nature of the fungus is another essential feature that limits the development of new antifungals. All these reasons support that fungal infections constitute a health problem yet to be solved; they also represent a challenge for basic and applied research where the identification of novel antifungal targets is extremely relevant. Understanding the mechanisms by which this fungus colonizes and causes disease is an important medical challenge and may provide ways to control its infections.

We intend here to highlight the main signaling pathways involving MAPKs in this organism. We will introduce, first, features related to the biology of this fungus regarding the recognition and immune response elicited by the host, and second, describe the main MAPK pathways characterized in this fungus and their connections with processes relevant in its biology, such as morphogenesis, cell wall construction and pathogenicity, as these processes represent an attractive target for the development of antifungal therapies. We refer the readers to other reviews which have outlined the role of these routes in other fungal models, not only *C. albicans* (Alonso-Monge *et al.*, 2009b; Román *et al.*, 2007; Qi and Elion, 2005; Chauhan *et al.*, 2006; Ikner and Shiozaki, 2005).

Introduction to *Candida albicans* Biology

Morphological Transitions

C. albicans was long considered to be a dimorphic fungus, that is, an organism that displays two different morphologies under different environmental conditions. The term dimorphic transition was coined to refer to the environmentally triggered conversion of yeast to hypha, which received substantial attention given its involvement in virulence (Mitchell, 1998; Whiteway and Oberholzer, 2004). However, it is a polymorphic fungus that can grow as yeast (unicellular), hyphae, pseudohyphae and chlamydospores (Fig. 1). Yeasts (also named blastospores) are ovoid cells, 3 to 6 μm in size, that reproduce in an asexual way by budding. Upon yeasts apical extension, germ tubes are formed which elongate in time originating cellular units separated by chitin septa, the hypha. In turn, hyphae can form yeasts by lateral budding (Odds, 1988). Pseudohyphal growth involves elongated cells that by a series of budding and separation remain attached to each other forming a chain (Gow, 1997). Under certain environmental conditions, as the absence of light, glucose limitation, low temperature and microaerophilia, thick-walled asexual structures, named chlamydospores, can be formed (Dujardin *et al.*, 1980; Montazeri and Hedrick, 1984). Although their biological function is unknown, they have been proposed to play a role in persistence (survival under unfavorable conditions) rather than dissemination.

Fig. 1 Distinct morphological states of *Candida albicans*. The picture shows the microscopic appearance of several morphologies present in *C. albicans*. The blastopore or yeast is the unicellular morphology of *C. albicans*, characterized by its elliptical form and asexual reproduction through budding. By bud elongation a pseudohypha or a germ tube (which eventually develops into a hypha) can be formed. While hyphae present cellular units separated by septa (with no constrictions) and with parallel cell walls, pseudohyphae are formed by elongated cells with constrictions at the position of septa and show regular branching. Chlamydospores are round or oval refractive cells with a thicker cell wall and are larger than blastopores.

The dimorphic transition (ie, the transition between yeast and hypha morphologies) can be induced by a range of environmental cues. High temperature (37°C over 30°C) has been shown to facilitate this conversion (Lee *et al.*, 1975). The pH of the medium also influences morphogenesis and at low pH (<6) *C. albicans* cells predominantly grow in the yeast form, while at a high pH (>7), hyphal growth is induced (Soll, 1986). Nutritional factors such as *N*-acetylglucosamine (Simonetti *et al.*, 1974), proline (Dabrowa and Howard, 1981) or serum (Gow and Gooday, 1982) have been revealed to influence yeast-to-hypha conversion. Morphogenesis has also been shown to be regulated by quorum sensing, a mechanism of microbial communication that is also present in this fungus (Albuquerque and Casadevall, 2012). Farnesol (Hornby *et al.*, 2001), tyrosol (Chen *et al.*, 2004) and dodecanol (Hogan *et al.*, 2004) have been all described as quorum sensing molecules acting via different modes of action in this transition (Hall *et al.*, 2011) and may explain why high cell densities impair hyphal formation.

The morphological diversity of *C. albicans* has special relevance in the biology of this fungus due to its implication in virulence and pathogenicity (Lo *et al.*, 1997). It is believed that the distinct morphological presentations are required to enable the fungal adaptation to the new environmental conditions found within the human host, and the rapid colonization of its tissues as well as to facilitate the development of the infection to the entire host organism (Romani *et al.*, 2003; Saville *et al.*, 2003).

In addition to dimorphism, *C. albicans* is able to display great morphological variability. This observation on *C. albicans* colonies stored on agar at room temperature or in cold rooms for extended periods of time, led to the definition, in 1985 (Slutsky *et al.*, 1985), of the term “phenotypic switching,” different from the yeast-to-hypha transition. This process is spontaneous and reversible and occurs only between two phases easily distinguishable by cellular morphology and staining with the dye phloxine B (Slutsky *et al.*, 1987). The white–opaque transition occurs at a relatively low frequency (approximately every 10^3 – 10^4 generations); however, it can be induced by certain environmental conditions (Morschhauser, 2010) such as the presence of CO₂ (Huang *et al.*, 2009), *N*-acetylglucosamine (Huang *et al.*, 2010), in anaerobic conditions (Ramirez-Zavala *et al.*, 2008) or by genotoxic and oxidative stress (Alby and Bennett, 2009). Although opaque cells had already been observed in 1987 (Slutsky *et al.*, 1987), only after the discovery of a mating-type locus (MTL) in *C. albicans* (Hull and Johnson, 1999) and the demonstration of its ability to mate (Hull *et al.*, 2000; Magee and Magee, 2000), the role of these cells in the fungal basic biology and pathogenesis, as well as the molecular mechanisms that regulate the white–opaque transition, became uncovered (reviewed in Soll, 2014).

Mating in *C. albicans* differs from other fungi. First, it requires that naturally frequent heterozygous cells at the MTL (a/α) become a/a or α/α . Second, MTL-homozygous cells must undergo an epigenetic switch from the predominant white to opaque phase, each cell type is heritable for many generations and switching occurs without a change in the DNA sequence of the genome

(Lockhart *et al.*, 2003). Opaque cells are the mating-competent form and are able to mate $\sim 10^6$ times more efficiently than white cells (Miller and Johnson, 2002). The tetraploid fusion product ($a/a/\alpha/\alpha$) then undergoes a random chromosome loss to generate recombinant progeny in a parasexual cycle (Bennett and Johnson, 2003; Forche *et al.*, 2008).

Rather paradoxical, the opaque phenotype is highly unstable at physiological temperature (Slutsky *et al.*, 1987; Rikkerink *et al.*, 1988), switching in masse to the white state when temperature is raised from below 25°C (optimal for opaque growth) to 37°C (Srikantha and Soll, 1993). This is in line with the fact that upon intravenously infection with these cells, mostly white cells were recovered from the kidneys of mice (Kvaal *et al.*, 1997). Nevertheless this is in agreement with the better colonization of skin (where temperature is lower) by the opaque phenotype. In addition, the presence of high levels of CO₂ (equivalent to those found in the host gastrointestinal tract and select tissues), *N*-acetylglucosamine (a monosaccharide produced primarily by gastrointestinal tract bacteria) and anaerobic conditions favor the white–opaque transition even at 37°C (Ramirez-Zavala *et al.*, 2008; Huang *et al.*, 2009, 2010).

Recently, other phenotypes have been also described in *C. albicans*. The passage through the mouse gastrointestinal tract triggers a novel phenotypic switch, resulting in the appearance of Gastrointestinally induced Transition (GUT) cells (Pande *et al.*, 2013). These cells differ from the opaque phenotype by the absence of pimples at the cell surface and the inability to mate. They seem to express a transcriptome that is optimized for the adaptation to the digestive tract. In addition, a “white–gray–opaque” tristable phenotypic switching system has been also discovered (Tao *et al.*, 2014).

Fungal Recognition by Immune Cells and Activation of Host Defenses

As a commensal, *C. albicans* growth and location within the host is controlled by the normal microbiota, epithelial barriers and the innate immune system with which the fungus is continuously or transiently interacting (Hoffmann *et al.*, 1999; Mochon *et al.*, 2010). Although this arm of the immune system lacks the specificity and memory that characterizes the adaptive response, it can also distinguish self from nonself: fungal recognition by the innate immune system implies the identification of pathogen associated molecular patterns (PAMPs) by the corresponding receptors (PAMPs Recognition Receptors, PRR) present at the surface of the immune cells. From this dynamic interplay immune responses are generated that can be either beneficial, maintenance of the commensal state, or deleterious, favoring damage by the yeast (Jouault *et al.*, 2009).

The fungal cell wall is rich in PAMPs and while cell wall proteins have the key role of adhesion to surfaces, polysaccharides dominate immune recognition and contribute to the immunological signature of *C. albicans* (Netea *et al.*, 2008). Cell wall proteins are also relevant as antigens and have been used, in the last years, for the development of vaccines (reviewed in Vecchiarelli *et al.*, 2012) such as the *N*-terminal domains of Als1, Als3 (Spellberg *et al.*, 2006) and Hyr1 (Luo *et al.*, 2010). Studies have also paid attention to the role of the polysaccharide β -glucan, and it has been shown that passive vaccination with anti- β -glucan monoclonal antibody can be used to confer protection against vaginal infection by *C. albicans* (Torosantucci *et al.*, 2005; Pietrella *et al.*, 2010).

The polysaccharides of *C. albicans* cell wall can be recognized by two major classes of membrane-bound PRRs: the Toll-like receptors (TLRs) and the C-type lectin receptors (CLRs). TLR2 and TLR4 recognize phospholipomannans and O-linked mannans respectively, and they are the main TLRs involved in the signaling induced by *C. albicans* (Tada *et al.*, 2002; Jouault *et al.*, 2003; Netea *et al.*, 2006). Mannans from the fungal cell wall can also be recognized by CLRs. Specifically, α -mannans (Saijo *et al.*, 2010) and hypha-specific high mannose containing structures (Sato *et al.*, 2006) are recognized by dectin-2, while *N*-linked mannans are recognized by macrophage mannose receptors (MR) (Netea *et al.*, 2006) and by dendritic cell-specific intercellular adhesion molecule 3-grabbing non-integrin (DC-SIGN) (Cambi *et al.*, 2008). CLRs play an important role in protective anti-fungal immunity (reviewed in Brown and Netea, 2012). Dectin-1 is also a CLR though it recognizes highly conserved β -glucans instead of mannans. Dectin-1 has been demonstrated to bind, in vitro, specifically to budding areas and bud scars of yeasts where β -(1,3)-glucan is more exposed, but not to hyphae (Gantner *et al.*, 2005). This result suggested that hyphae would be uniquely immune from dectin-1 mediated recognition; however, ex vivo results have shown that there is no morphotype-specific masking or unmasking of β -glucan (Wheeler *et al.*, 2008). An increased susceptibility of mice lacking dectin-1 to chemically induced colitis was described recently (Iliev *et al.*, 2012) which correlated with altered responses to commensal fungi.

Finally, other CLRs have been described. The soluble (not membrane-bounded) mannose-binding lectin (MBL), also recognizes mannans and mediates *Candida* opsonization and uptake (Brouwer *et al.*, 2008). The Mincle protein is a C-type lectin expressed predominantly on macrophages that was described to bind to *C. albicans*, although no specific ligand has been yet identified (Bugarcic *et al.*, 2008; Wells *et al.*, 2008). Galectin-3, a member of a β -galactoside-binding protein family, binds *Candida*-specific β -(1,2)-mannosides (Fradin *et al.*, 2000) allowing phagocytes to discriminate pathogenic from nonpathogenic yeasts and associates with TLR2 or dectin-1 upon macrophage–yeast interaction (Jouault *et al.*, 2006; Esteban *et al.*, 2011).

The recognition of *C. albicans* PAMPs by receptors of the immune system, leads to the activation of signaling pathways that ultimately stimulate cytokine production, phagocytosis and killing. The production of reactive oxygen species (ROS) is a major antifungal mechanism in phagocytes upon pathogen internalization (Missall *et al.*, 2004). Additionally, pathogens can be eliminated extracellularly through the action of secreted galectin-3 (Kohatsu *et al.*, 2006) and also by the release of antimicrobial peptides especially at the mucosa level, such as β -defensins, histatins (Hst 5) and cathelicidins (LL-37) (reviewed in Swidergall and Ernst, 2014). The innate response plays an essential role for the initiation and determination of the type of adaptive response that

Fig. 2 MAP kinase mediated signaling in *Candida albicans*. A stimulus is perceived through specific sensors or receptors at the plasma membrane and transferred through an adaptor module to the MAPKs central core. By sequential phosphorylation the signal is transmitted to the MAP kinase that is finally translocated to the nucleus where it phosphorylates a transcription factor or a transcription factor complex which in turn allows the expression of target genes. The different stimuli known to trigger *C. albicans* MAPKs are shown as well as the main processes in which each pathway is involved. However, this figure should be considered as general scheme and only the main response is outlined for each pathway. As indicated in the text, some pathways participate through direct or indirect mechanisms in the processes here indicated as well as others.

will be generated upon the microorganism invasion. Recently, the Th17 adaptive immunity (characterized by the production of IL-17 and several other cytokines, including IL-22 and IL-23) has been identified and it appears to be primarily responsible for protection against fungal infections at the mucosa (reviewed in [Hernandez-Santos and Gaffen, 2012](#)).

Fungal Adaptation Through MAPKs-Mediated Signaling

MAPK pathways are highly conserved among eukaryotic organisms ([Widmann et al., 1999](#)). They consist of a central module of three protein kinases that become sequentially activated by phosphorylation ([Kultz, 1998](#)): activated MAP kinase kinase kinases (MAPKKKs) phosphorylate MAP kinase kinases (MAPKKs), which in turn phosphorylate MAP kinases (MAPKs). These cascades mediate the transduction of signals perceived at the plasma membrane to the nucleus, where target genes are eventually regulated to allow the adaptive response ([Fig. 2](#)). The activating stimuli are first perceived by receptors (G-protein coupled receptors, histidine-aspartic phosphorylation sensors (two-component systems), integral membrane proteins or tyrosine kinase receptors) which transmit the signal to the MAPKs central core through upstream modules of intermediate proteins or adaptor molecules. The MAPKKKs, which are serine/threonine protein kinases become therefore, activated leading to the phosphorylation and activation of a MAPKK, which in turn stimulate MAPK activity. Each MAPKK can be activated by more than one MAPKKK, which is partially responsible for the interconnection or crosstalk among different routes ([Cargnello and Roux, 2011](#)). MAPKs (also called Extracellular-signal Regulated Kinases, ERKs) are dually phosphorylated on threonine and tyrosine residues within a conserved TXY motif (in which X represents glutamic acid, proline or glycine, depending on the MAPK) located in the activation loop of the catalytic subdomain VIII ([Hanks et al., 1988](#)). Upon activation, the MAPK usually translocates to the nucleus where the activation

(or repression) of the corresponding targets such as transcription factors or other molecules, triggers specific cellular responses required for adaptation.

The activation of the pathway is transient and negative feedback mechanisms exist, such as those mediated by the action of specific phosphatases (Martin *et al.*, 2005). There are also positive feedback mechanisms that lead to an amplification of the signal. Other mechanisms used by the cell to regulate the pathways are through scaffold proteins whose main function is to bring other proteins together for them to interact. In this way, they improve signaling efficiency and ensure that signals are connected to the correct response while maintaining the specificity of the pathways. MAPK substrate selectivity is also achieved by the existence of specific interaction domains (docking sites) (reviewed in Saito, 2010).

Different MAPK pathways have been identified and characterized in the pathogenic yeast *C. albicans* (Román *et al.*, 2007; Alonso-Monge *et al.*, 2006) through the isolation of the MAPK genes *HOG1* (San José *et al.*, 1996), *MKC1* (Navarro-García *et al.*, 1995), *CEK1* (Csank *et al.*, 1998) and *CEK2* (Chen *et al.*, 2002), and the phenotype analysis of mutants defective in them. These studies initially resulted in defining a role for each of these routes/MAPKs in fungal physiology. Thus, the high osmolarity glycerol (HOG) pathway has been shown to be responsible for sensing stress, the Mkc1 route for cell wall integrity, Cek1 for invasion and Cek2 for mating. However, given the several connections and crosstalk mechanisms among these routes and others present in the cell, this is now realized as an oversimplification with most of the MAPK pathways playing a very pleiotropic role in fungi.

HOG Pathway: Sensing Environmental Stress

In *C. albicans*, the HOG pathway has been associated to many fundamental processes such as morphogenesis, cell wall biogenesis, virulence, although predominantly, in the response and adaptation to stress (Alonso-Monge *et al.*, 1999, 2003; Smith *et al.*, 2004; Enjalbert *et al.*, 2006). Recently, its role on *C. albicans* response to arsenate and arsenite has also been uncovered (Urrialde *et al.*, 2015). In fact, the MAP kinase of the pathway Hog1 (homolog to Hog1 in the yeast *S. cerevisiae*) becomes activated in response to a variety of stimuli such as high osmolarity or oxidative stress, which occurs in a Pbs2-dependent manner (the pathway canonical MAPKK) through Ssk2 (MAPKKK) mediated signaling (Arana *et al.*, 2005; Cheetham *et al.*, 2007). The activation of the HOG pathway leads to glycerol accumulation (San José *et al.*, 1996), as occurs in *S. cerevisiae* (Albertyn *et al.*, 1994), which counteracts cell dehydration caused by hyperosmotic environments. The activation of this route upon oxidative stress (Alonso-Monge *et al.*, 2003) is of special importance in *C. albicans* as it constitutes a type of stress probably more related to the environment this fungus encounters during its life cycle within the host. Translocation of Hog1 to the nucleus due to oxidative stress generates an adaptive transcriptional response which is partially overlapping, although distinguishable, from the one generated by the transcription factor Cap1 (Alonso-Monge *et al.*, 2003; Enjalbert *et al.*, 2006), homologue of ScYap1 in *C. albicans* and shown to play a role in multidrug and oxidative stress resistance (Alarco and Raymond, 1999; Zhang *et al.*, 2000). Farnesol and caspofungin have been also described to activate Hog1 (Bamford *et al.*, 2009; Kelly *et al.*, 2009), indicating that both treatments induce oxidative stress in this fungus which is sensed by the HOG pathway. The downstream molecular mechanisms that underlie Hog1-mediated oxidative stress resistance remain an area of active research. The transcriptional repressor Sko1 mediates in part this oxidative response (Alonso-Monge *et al.*, 2010).

In *S. cerevisiae*, the HOG pathway is activated upon osmotic stress via two different upstream branches: the *SLN1*-branch which is a two-component system relying on *SLN1*, *YPD1* and *SSK1* genes to mediate the activation of the functionally redundant Ssk2/Ssk22 MAPKKs; and the *SHO1*-branch, the second input of this cascade, which converges at the Pbs2 MAPKK through the Ste20 PAK-like kinase (Posas *et al.*, 2000; de Nadal *et al.*, 2002; Hohmann, 2002). In contrast, although both branches do exist in *C. albicans*, only the orthologues of the mentioned genes for the *SLN1*-branch mediate the activation of Hog1 by oxidative stress (Chauhan *et al.*, 2003; Cheetham *et al.*, 2007). The *C. albicans* *SHO1*-branch is not involved in the activation of Hog1 but rather in the activation of Cek1, a homolog of the *S. cerevisiae* KSS1, upon osmotic stress (Román *et al.*, 2005). Deletion of upstream components of this pathway (mediated by Cek1), in combination with *SSK1*, does not impair activation of Hog1 or glycerol accumulation in response to osmotic stress, although cells remain sensitive to high osmolarity. Thus, although the *SHO1*-branch participates in the response to osmotic and oxidative stress, it does so through *HOG1*-independent mechanisms (Román *et al.*, 2005; Román *et al.*, 2009a). Integration of the oxidative stress response is, however, a complex process and the precise connections between the HOG pathway and other routes and oxidative defense mechanisms remain to be determined (Komalapriya *et al.*, 2015).

It has been also described the implication of the HOG pathway in different morphogenetic programs as well as in the biogenesis of the cell wall. Strains lacking genes from this signaling cascade such as *hog1*, *pbs2* or *ssk2* display enhanced true hyphal formation as evidenced under non-inducing conditions (Alonso-Monge *et al.*, 1999; Arana *et al.*, 2005; Cheetham *et al.*, 2007). In contrast, *ssk1* mutants show a reduced ability to filament even in the presence of serum, a phenotype that is not suppressed by *HOG1* overexpression (Alex *et al.*, 1998; Calera *et al.*, 2000). This is partially achieved via the activation of the Cek1-pathway (Eisman *et al.*, 2006), which promotes filamentation in this fungus. In addition, the Brg1 transcription factor and a positive regulator of filamentation, is expressed in *hog1*, *pbs2* and *ssk2* mutants independently of rapamycin, an activator of the TOR pathway, therefore suggesting that the TOR pathway is involved in hyphal elongation via the HOG pathway (Su *et al.*, 2013). Interestingly, *sko1* mutants, which are sensitive to oxidative stress and increase damage in *hog1* mutants, display increased filamentation (Alonso-Monge *et al.*, 2010). In addition to the yeast-to-hypha transition, Hog1 is also essential for chlamydospore formation, acting independently from Efg1 which was the first regulatory factor shown to be involved in this developmental

process (Sonneborn *et al.*, 1999). Both *efg1* and *hog1* are unable to form chlamydospores and overexpression of *EFG1* gene in a *hog1* mutant – and vice versa – did not restore the phenotype (Alonso-Monge *et al.*, 2003). Other genes that control chlamydospore development have been uncovered (Staib and Morschhauser, 2007). The Hog1 MAPK has been recently linked to another morphogenetic program in *C. albicans*, the white–opaque switching. In order to mate, homozygous cells for the MTL need to undergo an epigenetic switch from the standard white phenotype to the opaque and mating-competent state. The activation of the HOG pathway seems to be crucial for this process as the absence of Hog1, Pbs2 or Ssk2, as well as point mutations at the conserved phosphorylation sites of Hog1, increases the switching frequency and suppresses mating and pheromone-stimulated cell adhesion (Liang *et al.*, 2014; Chang *et al.*, 2016).

Regarding cell wall biogenesis, it was originally described that the deletion of *hog1* confers a resistant phenotype to certain compounds such as nikkomycin Z (which inhibits chitin synthesis) and Congo red or calcofluor white which alter the correct cell wall assembly (Alonso-Monge *et al.*, 1999; Román *et al.*, 2005). It has been proposed, based on transcriptional studies, that the HOG pathway regulates chitin synthesis coordinately with other pathways (Munro *et al.*, 2007). This could involve other MAPKs, such as Cek1, which has been also shown to be important in cell wall formation (Navarro-García *et al.*, 2005; Eisman *et al.*, 2006).

The HOG pathway also mediates metabolic adaptation in *C. albicans*. In fact *hog1* mutants are hypersensitive to inhibitors of the respiratory chain like azide and display an increased basal respiration, indicating that *hog1* mutants are more dependent on mitochondrial ATP synthesis (Alonso-Monge *et al.*, 2009a). Kaba and coworkers have further described a transient Hog1 phosphorylation under high iron concentrations, essential for the flocculent phenotype observed in a wild type strain, and a loss of viability of the *hog1* mutant when exposed to high concentrations of iron (Kaba *et al.*, 2013).

Since the HOG pathway plays so many crucial roles in the biology of *C. albicans*, it is not surprising the relevance of this pathway in fungal pathogenesis. In fact, though *hog1* mutants are hyperfilamentous (therefore, expecting to cause increased tissue damage), they show an attenuated virulence in a mouse model of systemic infection (Alonso-Monge *et al.*, 1999). A phenotype of *hog1* mutants that could explain this is their sensitivity to oxidative and nitrosative stress, even more pronounced in *pbs2* strains (Arana *et al.*, 2005). This could result in sensitivity to the phagocytic attack by macrophages and neutrophils which generate ROS or reactive nitrogen species (RNS) to allow fungal clearance (Missall *et al.*, 2004; Du *et al.*, 2005; Arana *et al.*, 2007). In addition, strains with a compromised HOG pathway are hypersensitive to some antimicrobial peptides such as the salivary cationic peptide histatin-5 (Hst 5) (Vylkova *et al.*, 2007) and β -defensins 2 and 3 (Argimon *et al.*, 2011). Hog1 (and Pbs2) have been also shown to play a critical role in the establishment of *C. albicans* in the mouse gut (colonization) which could be explained by their decreased adherence to the gut mucosa and/or sensitivity to bile salts (Prieto *et al.*, 2014).

Mkc1-Mediated Pathway: Maintaining Cell Integrity

The fungal cell wall suffers constant modifications in order to adapt to the different environmental conditions that *C. albicans* encounters. Defects in this adaptive response can lead to cell integrity loss which triggers a signaling pathway to revert the process (Blankenship *et al.*, 2010). The MAP kinase Mkc1 (homologue to Slr2/Mpk1 from *S. cerevisiae*) belongs to the so called cell integrity or PKC pathway. It has been demonstrated its role in cell wall biogenesis (Navarro-García *et al.*, 1995), in stress response (Navarro-García *et al.*, 2005), in morphogenesis (Navarro-García *et al.*, 1998), in biofilm formation (Kumamoto, 2005) and virulence (Díez-Orejas *et al.*, 1997). The cell integrity pathway includes a central module that incorporates the MAPKKK Bck1, the MAPKK Mkk2 and the MAPK Mkc1 (Alonso-Monge *et al.*, 2006) whose phosphorylation is dependent on the protein kinase C (Pkc1) which lies upstream of the MAPK core (Paravicini *et al.*, 1996; Navarro-García *et al.*, 2005). Functional studies using combined deletions of cell integrity and sterile vegetative growth (SVG) MAPKKs (*mkk2 hst7*) and MAPKs (*mkc1 cek1*) support a cooperative role for these pathways in regulating cell wall architecture under vegetative growth (Román *et al.*, 2015; Correia *et al.*, 2016). Mkc1 activation occurs in response to a wide range of external conditions such as cell wall damage, antifungal drugs and low temperature shocks (Navarro-García *et al.*, 2005). Mutants defective in *MKC1* present defects related to invasive growth under embedded conditions and in biofilm formation (Kumamoto, 2005) and are more sensitive to the action of cell wall degrading enzymes (such as zymolyase) and antifungals, developing superficial alterations in restrictive growth conditions such as high temperature (Navarro-García *et al.*, 1995). This pathway is especially relevant in the response of *C. albicans* to caspofungin. The echinocandins provide a safe and efficient therapy for systemic mycosis as they are noncompetitive inhibitors of β -(1,3) and β -(1,6)-glucan synthase which is involved in the synthesis of β -(1,3)-glucan, an essential component of fungal cell wall and absent from human cells. *C. albicans* can rapidly respond to the presence of echinocandins by elevating chitin content which has been described as a salvage mechanism of this fungus (Walker *et al.*, 2008). The chitin synthesis is coordinately regulated by the PKC, HOG and Ca^{2+} signaling pathways (Munro *et al.*, 2007) and, while both Mkc1 and Hog1 become activated in the presence of caspofungin, only calcineurin mutants and *MKC1* defective strains show a hypersensitivity to this compound.

This pathway has an important role in the cellular growth inside the host which is crucial for pathogenesis and Mkc1 is important for host interaction and fungal proliferation (Román *et al.*, 2007; Wachtler *et al.*, 2011). This kinase is also activated in response to oxidative stress, which is partially dependent on an intact HOG pathway (Navarro-García *et al.*, 2005). The fact that two MAPK pathways respond to oxidative stress reflects the relevance of this kind of stress in a pathogenic fungus (Herrero-de-Dios *et al.*, 2010). However, the absence of Mkc1 does not increase the sensitivity of *C. albicans* to killing by neutrophils or macrophages (Arana *et al.*, 2007), but does attenuate its virulence: *mkc1* mutants do not colonize target organs, and elicit an altered inflammatory response in infected animals (Díez-Orejas *et al.*, 1997).

Cek1-Mediated Pathway: The SVG Pathway

The Cek1 MAP kinase (homologue of ScKss1) was first identified by a functional screening with the aim of isolating *C. albicans* genes able to interfere in the *S. cerevisiae* pheromone-induced cell cycle arrest (Whiteway *et al.*, 1992). The pathway mediated by this kinase does indeed participate in the pheromone response, either through mating or biofilm formation, together with the MAP kinase Cek2 (homologue of ScFus3) (Chen *et al.*, 2002; Daniels *et al.*, 2006). The Cek1-mediated pathway is also involved in morphogenesis and hyphal formation, cell wall damage and glycosylation sensing (Monge *et al.*, 2006; Ernst and Pla, 2011); it also influences the response to oxidative and osmotic stress in *C. albicans* in cooperation with other pathways (Herrero-de-Dios *et al.*, 2010; Herrero de Dios *et al.*, 2013). Cek1 is activated through the MAPKKK Ste11 and MAKK Hst7 module (Csank *et al.*, 1998; Lee and Elion, 1999) and Cph1 works as a downstream effector (Liu *et al.*, 1994).

The pathway is also composed by other elements such as the Cst20 PAK (Leberer *et al.*, 1996), the upstream sensors Sho1, Msb2 and Opy2 (Román *et al.*, 2005; Herrero de Dios *et al.*, 2013; Román *et al.*, 2009b), and the VIH-type Cpp1 phosphatase that is believed to be involved in Cek1 dephosphorylation (Guhad *et al.*, 1998a). The elements of this cascade participate in the biogenesis of the cell wall through the so-called SVG pathway that promotes vegetative growth under basal (non-stressed) conditions. Strains defective in *CEK1*, *HST7*, *CST20*, *MSB2* or *SHO1* are susceptible to compounds such as Congo red, calcofluor white, echinocandins or the glucanase-enriched zymolyase (Román *et al.*, 2005; Eisman *et al.*, 2006; Arana *et al.*, 2009). The cell wall defects produced by the addition of either of these compounds or by specific mutations in cell wall genes, such in the ones related to *N* or *O*-glycosylation (Bates *et al.*, 2006; Cantero and Ernst, 2011; Ernst and Pla, 2011), lead to the activation of the pathway and ultimately to Cek1 phosphorylation. This process is mainly dependent on Sho1, except for tunicamycin-induced signaling (an inhibitor of bacterial and eukaryote *N*-acetylglucosamine transferases), which is specifically driven by Msb2 and cause an increase in the amount of Cek1 (Román *et al.*, 2009b; Román *et al.*, 2005). Cek1 can also be activated by iron and a role for Msb2 as an iron sensing protein has been hinted (Puri *et al.*, 2012). Cph1 (a target of Cek1) has also been described as an active chromatin remodeling transcription factor under iron-replete conditions (Puri *et al.*, 2014). Cek1, which is a short-lived protein, also responds to growth signals and is regulated by quorum sensing (Román *et al.*, 2009a). It becomes activated in conditions where an active growth is required, as the dilution in fresh medium of a stationary phase growing culture (resumption of growth). Induced cell wall remodeling upon Cek1 activation could explain, in part, the susceptibility of *C. albicans* cells to the antimicrobial peptide Hst 5 shown to bind to β -1,3-glucans exposed at the surface of the cell (Tati *et al.*, 2013). The induction of Cek1 phosphorylation, either by *N*-acetylglucosamine or serum, or its constitutive activation through deletion of Cpp1, increases the binding and uptake of Hst 5, rendering cells more sensitive to this antimicrobial peptide (Li *et al.*, 2015). On the other hand, a glyco fragment derived from the cleavage of the pathway sensor Msb2 is able to bind to Hst 5 and other antimicrobial peptides such as LL-37, human α - and β -defensins, mediating protection against their toxicity (Szafranski-Schneider *et al.*, 2012).

A morphogenetic role has been proposed for the Cek1-pathway: cells lacking some elements of this cascade such as *CST20*, *HST7* or *CPH1* are defective in hyphal formation on solid agar medium. In addition, *cek1*, although apparently normal in serum-induced liquid filamentation assays, is also required for this type of agar-invasive hypha formation where cells are first restrained in movement and nutrients may become limiting. In fact, nitrogen limitation has also been described as a triggering stimulus for the activation of this pathway (Köhler and Fink, 1996; Biswas and Morschhauser, 2005). The Sho1 adaptor and the Msb2 mucin were also described to play a role in agar invasion during starvation (Román *et al.*, 2009b) and it was demonstrated that Cek1 becomes phosphorylated during growth in contact to a semisolid surface, promoted in part by Dfi1, a plasma membrane protein (Zucchi *et al.*, 2010).

Contrary to Hog1, the Cek1-mediated pathway could exert a positive regulation on hyphal development, working in parallel with the protein kinase A (PKA) pathway. Activation of this latter pathway is dependent on the cyclic AMP (cAMP) and results in the phosphorylation of the transcriptional regulator Efg1 (Stoldt *et al.*, 1997; Bockmuhl and Ernst, 2001). In standard conditions, *efg1 cph1* mutants are totally incapable of forming filaments in vitro (Lo *et al.*, 1997), however, under hypoxia, Efg1 exerts a repressive role on hyphal development through the repression of the biosynthesis and activity of the Cek1 MAP kinase pathway (Desai *et al.*, 2015). Msb2 cleavage, which is necessary for Cek1 activation, has been related to biofilm formation (Puri *et al.*, 2012), while both Cek1 and Cph1 have been recently implicated in the process of pseudohyphal formation induced by sub-toxic concentrations of hydrogen peroxide (Srinivasa *et al.*, 2012).

Strains defective in elements of the Cek1-mediated pathway display a higher exposure of β -(1,3)-glucan at the cell surface with a consequent increase of the fungal cells binding to the immune receptor dectin-1, increase in phagocytosis and macrophage activation (Galan-Diez *et al.*, 2010). The *cek1* mutant is also associated to a reduced virulence in the mouse model for systemic candidiasis although it does not show hypersensitivity to macrophages or neutrophil-mediated killing (Guhad *et al.*, 1998b; Arana *et al.*, 2007).

Cek2: The Pheromone Response

The *CEK2* gene was cloned from an oligonucleotide probe-based screen used to find putative protein kinases from a *C. albicans* genomic library (Chen *et al.*, 2000). Additionally to the fact that shares 53% identity with *S. cerevisiae* Fus3, its expression is able to complement the mating defect of a *fus3 kss1* double mutant. Therefore, Cek2 is considered to be a functional homologue to ScFus3 and is implicated in the mating process of *C. albicans* (Chen *et al.*, 2002). Similar to *S. cerevisiae* where both MAPKs Kss1 (CaCek1 homologue) and Fus3 are necessary for an efficient mating, in *C. albicans* mating is also regulated by the orthologue protein kinase cascade in which Cek1 and Cek2 have an overlapping role. Although *cph1* and *hst7* mutants are totally incapable to mate, *cek1* has only a partial defect which becomes complete after the additional deletion of *CEK2* (Chen *et al.*, 2002; Magee *et al.*, 2002).

Opaque cells homozygous for the MTL locus can release pheromones that are sensed by opaque cells from the opposite mating type: opaque α -cells produce α -pheromone which binds to the Ste2 receptor on α -cells while opaque a-cells release a-pheromones which bind to the receptor Ste3 in α -cells (Bennett *et al.*, 2003; Tsong *et al.*, 2003). Upon pheromone sensing by the receptors, the signaling pathway is activated being responsible for the transduction of the pheromone signal to the nucleus to promote the appropriate transcriptional response. This cascade is composed by the trimeric G-protein complex (Cag1, Ste4, Ste18), the MAPK core Ste11, Hst7, Cek1 and Cek2 and the transcription factor Cph1 necessary to activate gene expression. As in *S. cerevisiae*, the mating pathway in *C. albicans* is composed by some of the genes that participate in the SVG pathway whose MAPK is Cek1. Furthermore, the same pathway is involved in the response of mating-incompetent white cells to pheromones released by opaque cells from the opposite mating type, culminating in enhanced biofilm formation (Daniels *et al.*, 2006). Because common elements are found in these pathways, specificity mechanisms such scaffold proteins must exist to prevent improper activation by environmental signals. The *C. albicans* gene *CST5* encodes the scaffold protein for the kinases in the pheromone response pathway of both opaque and white cells (Cote *et al.*, 2011; Yi *et al.*, 2011). Finally, orthologues of pheromone-inducible genes important for mating such as *FIG1* and *FUS1*, which encode membrane proteins activated by Cph1 or α -pheromone, have been also identified in the *C. albicans* genome (Tzung *et al.*, 2001).

The first transcription factor involved in pheromone-induced biofilms was Tec1, one of the transcription targets (along with Efg1 and Bcr1) for conventional (a/ α) biofilms. These biofilms in a/ α cells are regulated by the Ras/cAMP pathway and not by the MAPK-mediated signaling (Sahni *et al.*, 2010; Yi *et al.*, 2011). The mating-related transcription factor Cph1 was found to play a minor role in this process. However, recent results obtained by Lin and coworkers (Lin *et al.*, 2013) point to a new model in which the same MAP kinase components and Cph1 are responsible for signal transduction in both white and opaque cells. According to these authors, Tec1 would have a general effect on biofilm formation, not specific to pheromone stimulation.

Cek2 is considered to be under the repressive influence of the *a1/x2* complex, not being expressed on heterozygous strains for the MTL locus. Indeed, *CEK2* RNA was only detected in *MTLa* and *MTL α* cells in a northern blot analysis (Chen *et al.*, 2002). Accordingly, Srikantha and coworkers (Srikantha *et al.*, 2006) demonstrated through chromatin immunoprecipitation-microarray analysis (ChIP-chip) that *CEK2* holds an *a1* binding site. Moreover, Cph1 overexpression regulates both Cek1 and Cek2 in *MTLa* and *MTL α* strains but not *MTLa/x* (Chen *et al.*, 2002). The deletion of *CEK2* in *MTLa/x* does not affect *C. albicans* survival to human neutrophils nor the binding to the immune receptor dectin-1, an opposite behavior to strains defective in *CEK1* or *HST7* (Arana *et al.*, 2007; Galan-Diez *et al.*, 2010). Furthermore, the a/ α *cek2* mutant presents no defects in hyphal development on Spider and other inducing media (Chen *et al.*, 2002), again in contrast to other members of the MAP kinase cascade like Cst20, Hst7 (Köhler and Fink, 1996; Leberer *et al.*, 1996), Cek1 (Csank *et al.*, 1998) and Cph1 (Liu *et al.*, 1994). Therefore, not until recently, no significant phenotype for the *cek2* mutant had been described for the MTL heterozygous background. It has now been uncovered a cryptic role for this MAPK in cell wall biogenesis, as the absence of *CEK2* in a/ α strains leads to a moderate sensitivity to cell wall disturbing agents and Cek2 can actually become phosphorylated by the same stimuli that activate the SVG pathway (Correia *et al.*, 2016).

Conclusions

We have highlighted here the main processes in which MAPK pathway are involved to allow adaptation to the environment. They include, among others, metabolic changes, responses to stress, alterations in the cell wall and invasion of solid surfaces. All of them are essential to establish a successful interaction with the host, either via a commensal program or a pathogenic relationship. We believe that a close analogy can be established with the nervous system of a mammalian organism where the main functions are sensory input, data integration and motor output. For the *C. albicans* MAPK pathways here outlined, these three features are present as MAPK routes sense external stimuli by membrane receptors, integrate these data through defined biochemical events and finally generate a response via transcriptional adaptation. To ensure specificity, a variety of mechanisms exist such as the presence of scaffold proteins, a defined compartmentalization (nucleus, cytoplasm, membrane) and enzymatic substrate specificity that ensure that the proper response is generated in a timely fashion.

Although we have focused here only in the fungal pathogen *C. albicans*, they also play an important role in other clinically relevant fungi such as *Cryptococcus* (Bahn *et al.*, 2005) or *Aspergillus* (May *et al.*, 2005). They are also crucial in phytopathogenic fungi (Perez-Nadales *et al.*, 2014; Turra *et al.*, 2014) and therefore important to establish relationships with other living communities in the environment. The development of chemicals that may target these routes appear therefore as a promising way to control fungal proliferation in different environments. We believe this area of research will be relevant during the following years connecting clinical and basic research.

Interaction of Fungi With the host

Mycorrhizal interactions with plants is described elsewhere, therefore this chapter will focus on the communication between plants and fungal pathogens. Fungal plant pathogens can be classified as *biotrophs*, *necrotrophs* or *hemibiotrophs* based on their lifestyle and interaction with the host (Bais *et al.*, 2006). Hemibiotrophic fungi represent the most interesting group of pathogens since they use sequential biotrophic and necrotrophic infection strategies to invade and colonize host plants. Transition from the asymptomatic biotrophic phase, characterized by intercellular thick primary hyphae, to the destructive necrotrophic phase, characterized by thin filamentous secondary hyphae, is referred to as the biotrophy-necrotrophy switch. The host can tailor the defense response according to the changing phases of the pathogen by several mechanism. It can be observed a change at transcriptional level, and also in the phytohormone signaling involving JA, ET or SA (Battilani *et al.*, 2018; Beccaccioli *et al.*, 2019). They represent an integral component of host-defense system against several fungal pathogens. The lifestyle of a pathogen often dictates the host's defense strategy, and the pathogen may even manipulate hormonal crosstalk for successful colonization. Plants adopt timely activation of suitable phytohormone signaling depending on the pathogen's lifestyle to restrict the infection process. Necrotrophism involved the action of lytic enzymes and phytotoxins secreted by the pathogen, and is opposed to that of biotrophic fungi that feed on the live host, generally without the action of degradative enzymes or phytotoxins, developing a form of parasitism which does not lead to tissue death. However, it is important to highlight that during the infection process pathogenic fungi activate a first biotrophic phase necessary for the success of the infection, although in the case of necrotrophs this phase is very short and is associated with the very early stages of the interaction. Process of infection of hemibiotrophic fungi is characterized by a first biotrophic phase of variable duration, and by a subsequent necrotrophic colonization. These two strategies show crucial differences in the cycle of the disease, in the morphology of the infection, in the mode of acquisition of nutrients, in the manifestation of symptoms, in the range of susceptible hosts and in the plant defense responses.

Necrotrophic Fungi

Necrotrophic fungi infect plant tissues by killing host cells and feeding by dead plant tissues. When the host plant fails to counteract the initial events of the infectious process, these fungal pathogens cause the formation of necrotic areas that culminate in the death of the affected organ or the entire plant. This occurs thanks to their ability to secrete a variety of hydrolytic enzymes and phytotoxic compounds before and during the colonization of the host. Due to the high secretion of cell wall degradative enzymes (CWDE), some necrotrophic fungi cause typical symptoms of extensive and soft rot. Necrotrophic fungi can be classified as optional parasites for the method of feeding, in fact they can live saprophytically and overwinter in the absence of the host even on dead plant substrates (Berkey *et al.*, 2012).

Necrotroph infection process includes the conidia germination, host penetration through the formation of appressorium and secretion of pathogenetic enzymes, such as CWDE, or the entering through wounds, stomata or lenticels. The penetration determines the formation of a primary lesion, which expanding will trigger the necrosis of the host tissues and fungal sporulation. After penetration, the plant tissues are further attacked by many pivotal molecules named Reactive Oxygen Species (ROS) and by low molecular weight metabolites produced by necrotrophic fungi during the infectious process. These metabolites can be specific and characteristic only of plant-fungus associations, or they can consist of phytotoxic metabolites with a broad spectrum of action. Necrotrophic fungi are also able to manipulate the plant's immune system by suppressing its resistance mechanisms and influencing hormone levels through the biosynthesis of its own hormones, disrupting the network of molecular signals necessary for the activation of defense. The multiple virulence factors and the wide diversity of necrotrophic fungal species, in turn, determine variations in host resistance strategies, often linked to the activation of many resistance genes, hormones, secondary metabolites and PR proteins (pathogenesis-related). Infection and nutrient acquisition strategies by necrotrophic fungi differs greatly from that of biotrophs. In fact, many defense mechanisms specific for the biotrophs, such as the HR, are instead generally considered susceptibility mechanisms, which promote infection and colonization by necrotrophic fungi. Necrotrophic plant resistance is controlled by numerous genes. The symptoms of necrotrophic infection consist of extensive necrosis, rot and death of the plant, for biotrophs instead they manifest themselves as a slow and gradual deterioration of the host, without compromising its survival. Necrotrophic fungi can be distinguished in two groups based on the specificity of interaction with the host: (1) host-specific necrotrophs or HSN (Host Specific Necrotrophs) with a very limited range of hosts and (2) Broad-range Host Necrotrophs (BHNs) with a wide range of hosts. HSN necrotrophic fungi develop the infection and produce host-specific toxins which function as strain-specific effectors, essential for their virulence and infection process. An example of this grouping is *Cochliobolus carbonum* (anamorph: *Helminthosporium carbonum*) which produces the HC toxin and is capable of developing the disease known as "leaf

spot" only in susceptible maize genotypes. *Alternaria brassicicola* secretes a selective toxin or HST of a protein nature, known as toxin AB, and other phytotoxic metabolites of different nature such as Brassicicolin A, Brassicicenes A – F, Phomapyrone A/F/G. Host-specific resistance to these types of pathogens closely mirrors ETI and is based on the presence of proteins encoded by single genes capable of activating HST. The specific host toxin works as an effector because it suppresses the defense responses in sensitive hosts, but it is also essential for the host's response to attack. BHN necrotrophic fungi attack a wide range of hosts using lytic enzymes and toxins that are designed to knock out basic functions or common features to all plants. The fungal species that can be classified as BHN are very numerous and economically very important. Fungi that cause soft fruit rot, such as *Monilinia*, *Penicillium*, *Sclerotinia*, *Botrytis* and *Alternaria*, attack a large number of species. *Botrytis cinerea* is the most studied and known BHN because it is present all over the world, being a pathogen of numerous plants of agricultural interest. Different strains of *B. cinerea* can present various attack mechanisms that adapt to different hosts and tissues. *Sclerotinia sclerotiorum* is also able to attack a large number of hosts (more than 400) and is known to produce oxalic acid, an important virulence factor, together with several lytic enzymes such as glucanase, glycosidase, pectinase, cellulase, xylanase and protease. *B. cinerea* and *S. sclerotium*, together with the genera *Monilinia*, *Penicillium* and *Alternaria*, generally attack the aerial part of the host plant and spread through wind-blown spores or conidia.

Biotrophic Fungi

Biotrophs interact with other organisms and are unable to survive as isolated entities. The organisms involved can share the same space, or they can develop processes in which one or both partners take advantage and improve their reproductive success. Trophic relationships are often used to classify interactions between plants and microbes, when plants live during nutrient exchange with the pathogen, we speak of "biotrophic interactions" and we refer to microbes as "biotrophs" (Bonfante and Genre, 2015). Interacting with live plants requires very complex mechanisms. Biotrophs have the ability to manage and take control of the plant's immune system, manipulate the host's metabolism and redirect nutrients to own advantage. To maintain this relation, many microbial species possess secreted effector proteins that exert various activities in the host plant. Biotrophs have developed very complex mechanisms to access the nutritional resources present in plant cells, and molecular mechanisms aimed at undermining plant immunity. Furthermore, biotrophic fungi generate specific morphological structures adapted to extract nutrients from plant cells: these structures are called haustoria. These are extensions of the terminal part of the hypha which penetrate through the cell walls of plant cells without affecting the plasma membranes. However, biotrophs are not limited to the formation of haustoria. There are many apoplastic biotrophs that do not produce haustoria such as *Cladosporium fulvum*, the green-blue mold agent of tomato, and *Ustilago maydis*, agent of corn coal. In this case, exchanges between the host and the pathogen take place in the apoplast. Sometimes, apoplastic signaling may also be relevant in interactions in which haustoria are integrated, and they are called "endophytic" microbes. Once this space is occupied, some microbes seem to have lost their original ability to grow in a saprophytic way, and they are called "obligate biotrophs". Examples of these are some arbuscular mycorrhizal fungi, common powdery mildew and some rusts. Biotrophic pathogen must invade the host tissue with minimal damage and evade recognition by plant cells. This goal is achieved through three interconnected strategies: (1) creation of interfacial layers rich in carbohydrates and containing proteins that separate the fungal cell walls from the plasma membrane of plants; (2) production of effectors able to modulate the host metabolism and suppress its defenses; (3) fungal cell wall shaping to evade the immunity triggered by PAMPs. The plant immune system has evolved to face the biotrophic pathogens. The first step of immunity is the perception of molecules derived from pathogens (molecular patterns) by specific membrane receptors (pattern recognition receptors - PRR). A second level of plant defense (effector-triggered immunity, ETI) is based on the direct or indirect recognition of the effectors secreted by pathogens (avirulence proteins) by cytoplasmic sensors, so-called resistance proteins, also called NOD-like receptors (nucleotide-binding oligomerization domain), which usually confer specific resistance. This defense response often involves a reorganization of the cytoskeleton and a conspicuous secretory activity. Plant resistance is also accompanied by the presence of defense phytohormones (jasmonic and salicylic acid). Salicylic acid-mediated responses are considered typical of reactions to biotrophic attack, while those mediated by jasmonic acid and ethylene are thought to be associated with the response to necrotrophic pathogens.

This distinction is now being questioned, some data revealing the crucial signaling role of jasmonic acid in the indisputably biotrophic interaction of grapevine with downy mildew (*Plasmopara viticola*). There are two main strategies that plants use to limit the invasion and growth of biotrophic fungal pathogens: resistance to penetration and resistance mediated by programmed cell death (PCD). Plant strengthens the cell wall and membrane to inhibit spore germination and prevent the formation of haustoria (resistance to penetration). The second mechanism of resistance (induction of PCD) is activated within the penetrated epidermal cells and interrupts the supply of nutrients to the fungi by blocking the further development of the fungus.

Hemibiotrophic Fungi

Hemibiotrophic fungi are classified in the middle between the necrotrophic and biotrophic fungi, being able to adopt both survival strategies: they first exploit the biotrophic phase as the beginning of the infection and, subsequently, carry out a necrotrophic attack to grow rapidly and finally reproduce. The reality is that there is no clear separation between these different lifestyles, even if their classification is a useful exercise for the scientist (Chowdhury et al., 2017). For the agronomic importance, *Magnaporthe oryzae* together with the species belonging to the genus *Colletotrichum* represent today the most relevant models for the study of hemibiotrophic fungi. *Magnaporthe oryzae*, the causative agent of rice blast disease, is responsible for the most serious disease

affecting cultivated rice in the world. Instead, the genus *Colletotrichum*, composed of nearly 200 species organized in 14 phylogenetic groups, can infect a large number of plants of agronomic interest. Many phytopathogenic fungi develop a specialized structure, called the appressorium, to penetrate the plant epidermis. The appressorium can break the cuticle and the plant cell wall thanks to the high pressure and enzymatic action exerted on the host cell. During the biotrophic phase, the host's plasma membrane invaginates for the pressure exerted by the fungal hyphae, without penetration; at this stage, the host cell is still alive. The last phase of the infection, the necrotrophic one, involves the differentiation of thin hyphae which, growing quickly, kill and destroy the host tissues. The success of hemibiotrophic fungi, such as *Colletotrichum* sp. and *M. oryzae*, depends on the morphogenetic transition that allows them the formation of the appressorium and, therefore, the penetration of the host.

Host Sensing

How do Fungi Perceive the Host?

Fungi perceive their environment through light, chemical and physical signals. The perception of these signals activates signal transduction processes that induce changes in metabolism, cell organization and gene expression. These changes, in turn, lead to developmental and morphological processes such as sporulation and redirection of growth, induce the ability to degrade complex organic compounds and import nutrients and allow survival to stressful conditions: osmotic, oxidative, thermal stress and presence of antifungal substances. Pathogenic fungi, can synchronize all these responses as a result of the perception of the host in such a way as to be able to colonize it. All these responses can be modulated differently depending on the type of host or organ/tissue of the host attacked.

Plant Surface Detection

Pathogenic fungi that invade the above ground tissues (e.g., leaves, stems) recognize the surface of the plant, the cuticle, through its hydrophobicity and chemical composition. The cuticle is composed of cutin, a polymer of hydroxylated fatty acids and intracuticular and epicuticular waxes with complex compositions. In the pathogenic hemibiotrophic fungus *Magnaporthe oryzae* the membrane proteins Msb2 and Sho1 serve to recognize the rice cuticle (Christensen and Kolomiets, 2011). This molecular recognition leads to the formation of the appressorium. Msb2 is needed to detect hydrophobicity and cutin monomers while Sho1 is more important in the response to primary alcohols, which are the main components of waxes. Basidiomycete *Ustilago maydis* also depends on Msb2 and Sho1 for the development of appressoria on the surface of the maize leaf. Alongside the induction of appressoria, these surface signals induce the expression of effector genes associated with biotrophy (De Coninck et al., 2015). Some authors have shown that in *M. oryzae* Msb2 has overlapping functions with another mucin, Cbp1, in the formation of appressoria and that extracellular and cytoplasmic domains of Msb2 have distinct roles in appressorium formation and invasive growth. *Botrytis cinerea* requires Msb2 for the formation of appressoria or so-called "infection cushions" on harder surfaces (e.g., stem), even though *msb2* mutants of this fungus are still virulent in various plant species (Gao et al., 2007). The root invader *Fusarium oxysporum* does not encounter a cuticle but requires both Msb2 and Sho1 for invasive growth, root colonization and secretion of pectinolytic activity, apparently acting through the MAP kinase Fmk1 (Gebrie, 2016). Another radical pathogen, *Fusarium solani*, responds to cutin monomers by inducing the expression of a gene encoding for cutinase. The G-protein coupled receptor (G-protein) associated receptor, Pth11, is required for the development of appressoria in *M. oryzae* and is most likely involved in host surface recognition.

Cell Detection

By analyzing the gene expression of *Fusarium graminearum* (the causal agent of the Fusarium Head Blight in cereals) in the colonization of wheat kernels, a profound difference can be seen whether these are alive or dead. This suggests that the pathogen is able to specifically detect living plant cells. This has also been suggested by studies with the *F. oxysporum* effector gene SIX1, induced during root invasion but not in dead roots or by exudates or root extracts. Perhaps, living plant cells produce unstable compounds that are rapidly depleted after cell death and which can be detected by fungi. Another possibility is that living plant cells produce specific compounds only when they themselves detect the presence of microorganisms. An interesting example of the latter case is the accumulation of polyamine putrescine, a compound that in turn can induce the expression of genes such as *Tri5* that lead to the production of mycotoxin deoxynivalenol (DON) during the disease known as Fusarium Head Blight (FHB). If a polyamine is really the key factor for the activation of *Tri5*, it must be a very early response from the host because *Tri5* is already induced in the early stages of infection (in infection cushions).

Root Detection

In the soil, some fungi can sense the proximity of the roots through the compounds they release and respond by growing towards the source of those compounds, a process called chemotropism. A well-known example of a fungal response to compounds released by the roots is the branched hyphal response of arbuscular mycorrhizal fungi to strigolactones. Regarding pathogenic

fungi, a notable recent discovery is the response of the vascular pathogen *Fusarium oxysporum* to peroxidase released from the roots (described in the next paragraph).

Fungal Chemotropism

The term chemotropism is composed of the English word chemical and the Greek term *trépomai* “I turn around” and therefore designates a movement of organs in growth due to a chemical stimulus. In this paragraph, examples of fungal chemotropism directed towards the plant will be reported (Hemetsberger *et al.*, 2015). Chemotropism in this sense was reported for the first time in a work entitled “Comparative morphology and biology of fungi, mycetoza and bacteria” of 1887, in which Anton de Bary, considered the founding father of modern plant pathology, described the directional growth of the germ tubes of the fungus *Uromyces appendiculatus* towards the stomata of the bean leaves. The stimulus can orient growth towards its origin (positive chemotropism) or in the opposite direction (negative chemotropism), or have no effect. The ability of substances to generate the stimulus also depends on their concentration. Growing hyphae are exposed to various chemotactic signals of different nature which can be divided into fungal signals (pheromones), nutrients and signals produced by the host (plant). The latter phenomenon can be observed in the rhizosphere, or in that portion of soil that surrounds the roots of plants. Numerous interactions with bacteria and fungi take place in it, in fact it constitutes one of the most complex terrestrial ecosystems. Considering the extremes, mycorrhizal fungi provide plants with mineral nutrients and increase their chances of survival in nutrient-limiting environments. On the contrary, pathogenic fungi lead to yield losses. Hence, the survival of plants within this complex ecosystem depends on their ability to distinguish beneficial fungi from parasites. Likewise, fungal survival is also based on identifying suitable host plants and the ability to overcome the host's defenses. The chemical environment established by the roots of plants influences the microbial composition of the rhizosphere. Plants are able to produce both attracting and repellent compounds, the former allow the establishment of beneficial relationships with microorganisms, the latter keep parasites at bay. A variety of compounds that contribute to plant-fungus communication are released from the roots of plants in their surroundings, i.e., in the so-called rhizosphere. These include low molecular weight substances such as ions, free oxygen, amino acids, organic acids, sugars, phenols and other secondary metabolites, as well as high molecular weight exudates such as mucilages (polysaccharides) and proteins. The rhizosphere therefore attracts both beneficial and harmful microbes thanks to an environment rich in sources of organic carbon; on the other hand, some volatile organic compounds emitted by the roots of plants act as underground defense substances that exert antimicrobial and anti-herbivorous activity. Root exudates can be produced both constitutively (the so-called phytoanticipins) and in response to stimuli such as an attack by a pathogen (the so-called phytoalexins). In addition to contributing to the chemical warfare between plants and their pathogens, root exudates are equally important as signaling molecules in plant communication with symbiotic microbes. The colonization of the root by mycorrhizal fungi occurs following the perception of the root exudates by the pre-symbiotic fungal mycelium. Strigolactones have been identified so far as the compounds responsible for attraction to the roots; these, are plant hormones derived from carotenoids present in the exudates of plants of different taxa and can be considered general signaling compounds that are essential for the establishment of mycorrhizal symbiosis. In mycorrhizal fungi, strigolactones act as hyphal branching factors thus stimulating root colonization. Some of the substances produced by the roots following stress (e.g., wounds) or microbial attacks can be released into the rhizosphere and act as a booster for (other) pathogens. For example, within the 17 different classes of defense-related proteins (PR), which are activated following both biotic and abiotic stress, PR9s contain members of class III peroxidases. These enzymes are secreted by the plant into the rhizosphere following injury or microbial attack.

Turrà *et al.* (2015) have shown that the phytopathogen *Fusarium oxysporum* perceives the activity of plant class III peroxidase and reorients the growth of its hypha towards the roots (Fig. 1) (Gebrie, 2016). The pathogen will start its infection from the roots, and from these it can penetrate and colonize the plant. Through in vitro assays it was shown that the exudate from tomato roots, containing catalytically active class III peroxidases, had a positive chemotropic effect on the growth of *F. oxysporum*. As is the case in several eukaryotic organisms, fungi can sense environmental stimuli through surface receptors, which activate and transmit these signals through signaling mediated by mitogen-activated protein kinases (MAPKs). For pathogenic fungi, the ability to perceive suitable hosts is crucial for parasitism. Thus, surface receptors and downstream signaling pathways specialized during the evolutionary process to detect nearby host plants. To identify the signaling pathway responsible for host perception (MAPK pathway) triggered by peroxidase, deletion mutants on the *F. oxysporum* MAP kinases were generated. The characterization of these mutants revealed that *F. oxysporum* exhibits several MAPK signaling pathways, specialized on the basis of the perceived stimulus which can be nutritional, linked to the mating type, or elicited by peroxidase. The study of the mutants highlighted a further discovery, namely that the same receptors responsible for the recognition of pheromones (which determine the mating type), were involved in the signaling elicited by peroxidase. *F. oxysporum*, like many other pathogenic fungi, enters the host tissue through the root wounds. When lesions occur in plant tissues, the production of reactive oxygen species (ROS) is triggered. The release of peroxidases, in the damaged sites, increases the toxicity towards the pathogens that are invading the tissue. Therefore, type III peroxidases, in addition to being linked to plant defense, are able to carry the pathogen towards the injured site of the host plant. It remains to be determined whether this concept can be generalized.

However, there remain some questions whose answers are still incomplete, for example it is not clear how *F. oxysporum* resist the antimicrobial activities of the plant, and if there is a mechanism that is able to tolerate this toxic environment for the pathogen. For root pathogens there is no evidence in this regard, but it is known that leaf pathogens to fight the defense responses of the

Fig. 1 Plant-pathogen interaction model. The fungal hyphae grow towards plant cells following the perception of peroxidase (first signal) which is perceived by specific receptors capable of activating the phosphorylative cascade in which the Mpk1 kinase is involved. Hyphae are stimulated to grow directionally in virtue of the oxidizing environment that is generated following the release of reactive oxygen species (ROS). Additional compounds released into the environment such as oxylipins, nutrients and hormones can act as a secondary stimulus of directional growth of the fungal hypha.

plant have evolved the ability to secrete molecules, enzymes and proteins known as effectors that alter the physiological processes and subvert the immune defenses of the plant. host plant, contributing to virulence. For example, the rice phytopathogen *Magnaporthe oryzae* produces a preserved glutathione peroxidase that neutralizes the hydrogen peroxide produced by plants. Fungal mutants, devoid of glutathione peroxidase, are more sensitive to reactive oxygen species, such as hydrogen peroxide, and are also altered in virulence. These enzymes are very conserved in filamentous fungi therefore it will be interesting to determine if *F. oxysporum* has a similar detoxification system. Another pathogen advancement mechanism that interferes with peroxidase has evolved in *Ustilago maydis*. An effector protein, called Pep1, secreted by *U. maydis* was found capable of inhibiting the activity of type III peroxidases and suppressing the oxidative burst during the first moments of the immune response. Like peroxidases, Pep1 also appears to be conserved in all carbon-causing biotrophic pathogens such as *U. maydis*.

In conclusion, the host-pathogen interface appears to be an area rich in interactions and signals conveyed by the environment, therefore understanding the chemotropic mechanisms underlying the recognition and progression of pathogenesis is essential for determining the fate of the coexistence of different organisms.

How Plants and Fungi Communicate

By-Passing Plant Defenses

Once recognized the host, fungi can enter the host only if able to bypass its defenses. In fact, beside the features of the pathogenic fungi discussed below, they can express or secrete molecules that trigger immune regulatory mechanisms; indeed, fungi can produce effectors that can modulate the plant immune system to their own advantage. To be pathogenic, fungi must access inside the plant, either directly through the leaf or root surface or through natural wounds or openings such as stomata. The first barrier for the infection is represented by preformed structural (i.e., cell wall of the plant) and biochemical defenses (i.e., phytoalexins). Furthermore, plant cells can quickly recognize a potentially dangerous microorganism and activate a wide range of responses aimed at killing it and limiting its spread in the host. Plants do not have circulating immune cells and do not have an adaptive immune system as in vertebrates; instead, each cell is able to recognize the presence of a pathogen, through autonomous biochemical mechanisms that resemble the innate immune system of animals. For this reason, we often talk about the innate immunity of plants to describe the complex of defense responses that are rapidly induced at the site of infection (Hogenhout *et al.*, 2009). Subsequently, longer-term responses may be observed not only in tissues directly in contact with the pathogen, but also in the rest of the plant, and acquired resistance to subsequent infections may occur. The immune response in plants consists of a general response triggered by pathogen-associated molecular pattern (PAMP) and a specific response triggered by effectors. The first type of response is known as PAMP triggered immunity (PTI) and the second as effector triggered immunity (ETI). Jones and Dangl (2006), developed a simplified model to explain the evolution of PTI and ETI in plants, known as the “zigzag model”. This model is based on the results of previous studies carried out on plant interactions with biotrophic pathogens. According to the model, the first defense response is the PTI activated by PAMPs released by pathogens. Successful (hemi)biotrophic pathogens secrete effectors within the host cell, some of which can suppress PTI while others reprogram the physiology of the plant to promote host colonization. The host may possess resistance proteins (encoded by R genes) that can detect specific effectors or

monitor their activities, resulting in activation of ETI, a much more effective response and often (but not always) associated with the hypersensitive response (HR). These defenses are orchestrated by the tight relation among – at least – three defense-related hormones: jasmonic acid, salicylic acid and ethylene. In phase one of the HR, the activation of R genes triggers an ion flux, involving an efflux of hydroxide and potassium to the outside the cells, and an influx of calcium and hydrogen ions into the cells. In phase two, the cells involved in the HR generate an oxidative burst by producing reactive oxygen species (ROS), superoxide anions, hydrogen peroxide, hydroxyl radicals and nitrous oxide. These compounds affect cellular membrane function, in part by inducing lipid peroxidation. More generally, HR is a multifaceted response in which ROS, phytoalexins and PR proteins *inter alia*, are secreted into apoplast to challenge fungal invasion; fungi have to face these molecules to entertain a symbiotic (parasitic) relation with the host.

Lipid Signaling

When the pathogen and the host are in contact, an alteration of the composition of fatty acids occurs in both organisms. This alteration can be caused by the remodulation of the intake of fatty acids and the activity of enzymes involved in their synthesis and degradation. The expression of the lipid metabolism genes is induced during the host infection with consequent modification of the lipid profile. Enzymes that modify lipids regulate the production of lipid metabolites and consequently signal transduction and cell growth (Battilani *et al.*, 2018; Beccaccioli *et al.*, 2019).

Fatty Acids

Fatty acids are the building block of the lipid metabolism, they can be present as free fatty acids or can also be part of more complex lipid molecules such as acylglycerides, phospholipids and sphingolipids. The class of phospholipids includes phosphatidic acid (PA), phosphatidylserine (PS), phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylglycerol (PG) and phosphatidylinositol (PI). The lipid molecules can be the substrate for different enzymes, such as the lipases secreted by different phytopathogenic agents that act as virulence factors; phospholipases generate molecules derived from phospholipids which are crucial signals in plant-pathogen interactions and act as modulators of many signal transduction pathways during plant-pathogen interaction. Changes in the content of phospholipids and the activity of phospholipases in the plant activate the defense and resistance responses to necrotrophic pathogens. Plant phospholipases are traditionally classified into phospholipases A, C or D, based on the location of the glycerolipid breakdown site. Phospholipase D (PLD) catalyzes the hydrolysis of PC to generate choline and PA; phospholipase C (PLC) generates two intracellular messengers, diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP3), which respectively mediate the activation of protein kinase C and the intracellular release of calcium. Phospholipases A1 (PLA1) and A2 (PLA2) can remove acyl groups by accumulating free fatty acids. During the pathogen-host interaction, PLD and PLA1–2 release free fatty acids deriving from phospholipids. In *Arabidopsis thaliana*, oleic acid modulates defense responses while trienoic acids (16:3 hexadecatrienoic acid and 18:3 α -linolenic acid) activate defense responses against bacterial pathogens. Long-chain (LCFA) and very long-chain (VLCFA) fatty acids are present in the endoplasmic reticulum, they are generated by the addition of carbon units to the acyl chain. This function is performed by enzymes called elongases that are distinguished in Elo1,2 and 3. Desaturases (Fad), which also includes Ole1, lead to the formation of mono and polyunsaturated fatty acids (PUFAs, Poly Unsaturated Fatty Acids). The Sct1 enzyme is an Ole1 competitor which acts by reducing the formation of PUFAs. Fatty acids can also be incorporated into complex lipids (phospholipids, acylglycerols and sphingolipids).

Oxidized Fatty Acids: The Oxylipins

Fatty acids also represent the substrates for the formation of oxylipins, a family of compounds with distinct hormonal functions, involved in the host-pathogen interaction. The oxylipins constitute a large family of oxidized fatty acids, they are present in mammals, plants, bacteria and fungi. Oxylipins can regulate growth and mediate biotic and abiotic stress responses in all living organisms. They have been extensively studied in plants; in fact, they are produced by plants in several defense responses to deal with infections caused by different pathogens. Plant oxylipins include hydroperoxides of fatty acids, hydroxyl-, epoxy-, keto and oxy- fatty acids, epoxy alcohols, divinyl ethers, alcohols, volatile aldehydes, jasmonic acid (JA) and its derivatives. All these compounds are synthesized enzymatically or not. In higher plants, 18:2 linoleic acid and 18:3 α -linolenic acid represents the most abundant PUFAs. PUFAs readily react with O₂ which generates hydroperoxides in membrane lipids influencing membrane fluidity. The oxidative burst, or a rapid and transient production of ROS (Reactive oxygen species), is one of the first events activated during the defense mechanisms of plants during plant-pathogen interaction. ROS can oxidize PUFAs and form oxylipins. To limit oxidation reactions, reducing potentially harmful effects, cells have developed a wide range of antioxidant defense systems. In lipids with 18 carbon atoms, the greater the number of C = C double bonds, the greater the reactivity, i.e., the greater the possibility of being oxidized. 18:3 α -linolenic acid is more unstable than 18:2 linoleic acid, which in turn is more unstable than 18:1 oleic acid. The biosynthetic pathway of oxylipins usually begins with a fatty acid peroxidation reaction which is catalyzed by lipoxygenases (LOX). Fatty acid hydroperoxide can be subsequently converted by enzymes belonging to the cytochrome P450 family.

Sphingolipids

Sphingolipids are involved both in the maintenance of cellular structure and in the control of cellular homeostasis. This lipid class has been studied primarily in mammals, since sphingolipids are involved in cell proliferation, in the response to stress and in apoptosis. However, their study has also been deepened in plants, as they are fundamental in some processes such as the development of pollen, and in the response to biotic and abiotic stress. In recent years, the role of sphingolipids has also deserved attention in pathogenic fungi. The main investigations were carried out on the involvement of sphingolipids in signaling processes, growth and virulence (Maor and Shirasu, 2005). The synthesis of sphingolipids in pathogenic fungi is widely conserved between species, it occurs in the endoplasmic reticulum, from which they are transported to other organelles or are directed towards the plasma membrane. Structurally the sphingolipid is composed by a sphingosine, an unsaturated amino-alcohol with a long chain, linked to a fatty acid through an amide bond; this structure is defined as ceramide (Cer). The enzyme that catalyzes the amide bond is Ceramide Synthase (CerS). In mammals there are six isoforms of CerS that can bind different fatty acids to sphingosine. A further determinant of diversification is represented by the degree of hydroxylation (i.e., the presence of hydroxyl groups $-OH^+$) in the fatty acids and in the sphingoid bases. The heterogeneity in the structure of sphingolipids is also generated by the possibility of binding different components, such as carbohydrates and phosphatidylinositol. Sphingolipids play an important role in controlling the host-pathogen interaction. Pathogens can produce sphingolipids that are not present in the host, they can be considered infection markers. However, the plant has developed a defense system that involves the production of antimicrobial proteins, called defensins, which are released upon recognition of these sphingolipids. In fact, certain sphingolipids, such as glycosylated ones, elicit the defense responses of the plant.

Sphingolipids Main Component of Lipid Rafts

Sphingolipids are essential components of lipid rafts which together with sterols generate these highly dynamic membrane microdomains. In mammals the main sterol is cholesterol, while in fungal lipid rafts the main components are glycosphingolipids and ergosterol. Lipid rafts are involved in dynamic membrane processes, such as protein sorting, polarized growth, and secretion processes, however they are also essential in terms of cell recognition and signaling. There are several evidences of the detection of lipid rafts, in *Saccharomyces cerevisiae* yeast they were detected through selective staining for sterols, which were detected on the hyphal extremities in the presence of pheromone. Lipid rafts have also been identified in fungal pathogens *Cryptococcus neoformans* and *Aspergillus nidulans* during polarized morphogenesis processes. The composition of lipid rafts is fundamental, in fact the presence of ceramides stabilizes the structure and has important physiological consequences, such as involvement in cell signaling processes. Lipid rafts are characterized by reduced lateral mobility, a change in membrane thickness and a composition different from other parts of the membrane. This latter feature seems particularly important in allowing these domains to play a role in protein sorting. In fact, several studies indicate that a change in the composition of lipid rafts generates the reorganization of membrane proteins, therefore these domains could be the preferential sites of interaction between host and pathogen.

How Fungus-Host Communication can Influence the Virulence and the Secondary Metabolism

Mycotoxins are toxic fungal products that are produced when fungi grow in human and animal foods. For plant pathology, mycotoxins are pathogenicity or virulence factors, i.e., they play a role in causing or increasing the plant disease (Mengiste, 2012). On the other hand, there is relatively little evidence that mycotoxins enhance the ability of fungi to grow in vertebrate hosts. *Aspergillus*, *Alternaria*, *Claviceps*, *Fusarium* and *Penicillium* are the main mycotoxigenic fungi. Exist several mycotoxins (about 300–400 different mycotoxins have been recognized) that differ from each other structurally and in their toxicity. Most are not of significant dangerous in terms of human health, although aflatoxin B1 (AFB1) is well known for its health impact.

Several fungal pathogens can produce toxic secondary metabolites, mycotoxins. Some of them interfere with the host's sphingolipid metabolism, as shown below. Necrotrophic pathogens can control the activity of CerS through mycotoxins, as does *Alternaria alternata* f. sp. *lycopersici*, a tomato pathogen, which produces the toxin AAL structurally like sphingosine. This inhibition leads to a metabolic imbalance. ALL causes accumulation of sphingoid bases that induces programmed cell death (PCD). Similarly, to the AAL toxin, fumonisins (FBs) produced by the genus *Fusarium* can inhibit the activity of CerS in mammals and plants by inducing cell death. Therefore, the toxins AAL and FB can induce PCD by inhibiting CerS; this mechanism is a virulence strategy of some pathogens suggesting a close link between sphingolipid metabolism and plant PCD. The toxin AAL, produced by *Alternaria alternata* f. sp. *lycopersici* and fumonisins, produced by several *Fusarium* species belonging to necrotroph fungi. These toxins inhibit the ceramide synthase, causing the increase of long chain bases, essential for the ceramide's formation. That increase conduct the cell towards PCD.

The lipid-based communication between the plant and fungus depicts a scenario where the pathogen hijack the plant lipid metabolism to adapt to plant defenses and re-shape the host cell "landscape" to growth pathogenically and eventually kill the plant (Jones and Dangl, 2006). This phenomenon occurs in the widely studied ear rot of maize caused by *A. flavus* or *F. verticillioides*. Notably, *F. verticillioides* overrides defenses of susceptible maize lines by using oxylipin effectors to hijack host oxylipins pathway; essentially shutting down the most effective defense against this pathogen that is JA-based cit "JA-deficient opr7opr8 double mutant displayed extreme susceptibility to *F. verticillioides*. Notoriously, JA orchestrate plant defenses mainly

Fig. 2 *Fusarium verticillioides* produces 8-HpODE from LDS1. This fungal 8-oxylipin, likely by mimicking maize oxylipins, represses the JA-producing ZmLOX12 whilst activating the 9-oxylipin producing ZmLOX3. 9-oxylipins may induce FB synthesis. Thus, *F. verticillioides* infects maize and produces fumonisins (FBs). FBs disrupt sphingolipid biosynthesis in the host (*A. thaliana*) by inhibiting the enzyme ceramide synthase. In maize, this disruption increases the concentration of LCFA ceramides and decreases the concentration of VLCFA ceramides that, in turn, may activate Mitogen-activated Protein Kinase 6 (MPK6) a molecular controller of salicylic acid (SA) synthesis. SA turns on defense and programmed cell death (PCD) responses in the maize cell such as PR1 and McaII (type II metacaspase). This cell landscape may support the necrotrophic growth of *F. verticillioides* into maize tissues. Reproduced from Saucedo-García, M., Guevara-García, A., González-Solís, A., *et al.*, 2011. MPK6, sphinganine and the LCB2a gene from serine palmitoyltransferase are required in the signaling pathway that mediates cell death induced by long chain bases in Arabidopsis. *New Phytologist* 191, 943–957.

upon necrotrophic pathogen insults. After avoiding host defenses through 8-HpODE, *F. verticillioides* induces the host to produce 9-oxylipins (Mengiste, 2012).

It has been recently discussed the role of oxylipins as signal molecules: fungi – i.e., *Aspergillus* spp.- recognize host 9-H(P)ODE through a GPCR mediated cascade pathway (Niu *et al.*, 2020). Downstream this, the global regulon of secondary metabolism (i.e., by acting through *LaeA*) is switched on. In *F. verticillioides*, 9-H(P)ODE trigger the synthesis of fumonisins (Risipail *et al.*, 2009) that as stated above can – acting, differentially, on ceramide synthases (notably activating LOH2 and repressing LOH1–3) –re-shape the sphingolipids of maize kernels by enhancing S-LCFA and depressing S-VLCFA: these perturbations enhance SA biosynthesis that in conditions of JA-repression could lead to the PCD observed during necrotrophic colonization of host tissues (Fig. 2).

Fungi such as *Parastagonospora nodorum* use effectors such as SnToxA for eliciting PCD in wheat leaves which likely aid the switch from an epiphytic to endonecrotrophic growth. Here we suggest FBs as factors supporting *F. verticillioides* virulence allowing it to switch from an endophytic to a necrotrophic lifestyle. This probably is needed for infection of adult plant tissues (e.g., roots) and possibly for the movement of the fungus through the plant into kernels.

Introduction to Filamentous Plant Pathogens

The importance of fungi is well acknowledged, since they play important ecological roles, as recycling carbon and mobilizing nitrogen, phosphorus and other bio-elements, support (endophytes, mycorrhizal fungi) or threaten (plant pathogens) plant life (Naranjo-Ortiz and Gabaldón, 2019). Besides the paramount importance of ecological features of fungi, the negative impact of many fungal species on cultivated plants has been recognized starting from the ancient centuries until recent period, when fungal epidemics have had significant social and economic impact. Fungal taxonomy has deeply evolved since the first classification of Linnaeus as belonging to the “Regnum Vegetabile”. Phylogenetic relationships of the Kingdom Fungi can be inferred by means of several characters (fossils, comparative morphology, and biochemistry), although most modern phylogenetic trees (evolutionary trees, or cladograms) depend on molecular data coupled with these traditional forms of data. The main and most accepted features defining the Kingdom Fungi are represented by chitin as the major component of fungal walls; ergosterol in cell membranes; synthesis of lysine by a unique pathway and others reviewed in Webster and Weber (2007), Gould (2017). Based on these assumptions, recently the Oomycota are no more recognized as true fungi (Fry and Grünwald, 2010). Oomycetes grow filamentously and feed osmotrophically, so they look and behave like fungi and for these reasons have been thought to be part of the Kingdom Fungi. However, phylogenetic analysis has shown that they are part of the Chromista (Stramenopile) phylum, which includes a range of different forms such as diatoms and kelps. The class Oomycota encompasses a wide diversity of microbial forms, from free-living saprobes to parasites of plants and animals. The class contains some of the most important agricultural parasites of plants (like *Phytophthora*) that cause a range of pathologies, including blights, cankers, wilts, rusts, lesions, and rots.

The assumption that Fungal Kingdom is monophyletic (meaning that all modern fungi can be traced back to a single ancestral organism) has been recently debated; the synapomorphy that separates them from other groups sometimes is not accepted since new common characters are found in different phylogenetic taxa, and additional evidences are recently available after the release of whole genome sequences of many fungi (Richards *et al.*, 2017). As widely recognized, the Kingdom Fungi includes four-phylum (Ascomycota, Basidiomycota, Zygomycota, and Chytridiomycota). The first two are grouped into the monophyletic lineage Dikaria, while the latter were found to be polyphyletic (Tanabe *et al.*, 2005). Even if subject of recent revisions, the classification of fungi based on their pathogenic lifestyle and the way they feed on the host lifestyle is widely accepted (Doehlemann *et al.*, 2017). On one side are positioned the biotrophic, including obligate (rusts and powdery), and non-obligate (smuts and some *Claviceps*) that depend on their host for completion of their life cycle. To the other side, the necrotrophs are divided into true necrotrophic pathogens, which attack and kill healthy plants, and secondary necrotrophic-like pathogens, which are saprophytic in nature but may occasionally infect plants that have been previously weakened, e.g., by abiotic stresses or other pathogens (Agrios, 2009).

As pathogens of plants, fungi and oomycetes behave similarly and present the same problems so they are usually referred as filamentous plant pathogens.

There is no general agreement about what species are, and some currents of thoughts casts doubt on the existence of a species category in nature, at least as prokaryote are concerned, suggesting that the several proposed Species Concepts should be considered as species criteria and that species correspond to segments of evolutionary lineages that evolve independently from one another (de Queiroz, 2007; Giraud *et al.*, 2008; Ereshefsky, 2010). One of the most important character at the base of speciation in sexually reproducing fungi is the emergence of barriers to gene flow, i.e. mechanisms that prevent mating from spreading genes from one group of organisms into another, both in different geographic areas (i.e., “allopatric divergence”) but also without geographic separation (i.e., “sympatric divergence”). In this case, fungi could mate only on their host plants or within their specialized substrate (Giraud *et al.*, 2008). In fungi lacking apparent sexual stage, other strategies are used in order to exchange genetic material (recombination, whether sexual, parasexual, or hybridization) (Taylor *et al.*, 1999; Stukenbrock, 2016; Drenth *et al.*, 2019).

The deep changes in an agricultural ecosystem (denser and genetically more uniform hosts, cultural practices, rapid exchanges of vegetable materials, climate changes), greatly affect the rate of evolutionary changes in fungal populations as compared to a natural ecosystem (McDonald and Stukenbrock, 2016). Knowledge of the reproductive biology of pathogens and of the mechanisms by which populations acquire genes and increase genetic diversity are of paramount importance in defining the genetic structure of a fungal population, intended as the amount and distribution of genetic variation within and among populations. These studies, based on the use of genetic “neutral” markers, allow for understand the role of the forces that shape the genetic structure of a population and, most interesting, consent to obtain insight into the future evolutionary potential of pathogen populations (McDonald and Linde, 2002). In recent years, population genomic studies based on whole genomic data of filamentous phytopathogenic fungi, through genotyping a very large number of loci or re-sequencing of many isolates, are gaining deeper insights into the biology, genetics, and evolution of plant pathogens, deciphering the adaptation or the divergence of closely related taxa, or the genetic basis of phenotypic variation and evolutionary change (Grünwald *et al.*, 2016; Stajich, 2017).

Table 1 Comparison of genome size and no. of genes in Ascomycota, Basidiomycota and Oomycota

<i>Fungal division</i>	<i>Average Genome size (Mb)</i>	<i>Average No. Of Genes</i>
Ascomycota	36.91	11,000
Basidiomycota	46.48	15,000
Oomycota	74.85	24,000
Mucoromycotina	38.77	13,000

Large-Scale Genome Dynamics: Evolution of Size

Filamentous plant pathogen genomes vary greatly in their organization and composition. In fact, compared to the size of animal genomes, and in particular to plants, fungal genome size may be quite smaller (Tunlid and Talbot, 2002). The yeast *Saccharomyces cerevisiae* genome, has been the first fully sequenced eukaryotic genome in 1996 (Goffeau *et al.*, 1996), with a genome slightly larger than 12 Mb. Indeed, genome size of filamentous plant pathogens can vary by almost 3 orders of magnitude: sequenced genome range in size from ~2 mega-bases (Mb) in Microsporidia to 2 giga bases (Gb) in Pucciniales, with a median of 35 Mb (Table 1).

Interesting, the larger fungal known genome belongs to *Entomophaga aulicae*; the genome size is estimated to be as large as 8 Gb based on estimates using nuclear staining approaches, although genome sequencing has not yet been attempted (Stajich, 2017).

The variation in the size and contents of genome has been considered to emerge as a consequence of the differential degree of genetic drift and therefore the efficacy of selection, acting on genomes. Under this “mutation-hazard” (MH) model, species with small effective population size have larger genomes because they can tolerate the slightly deleterious accumulation of extra DNA in the form of transposable elements, multiple introns and gene duplication (Kelkar and Ochman, 2012). The negative association between genome size and population size seems to hold across a wide range of eukaryotes, including fungi (with some exception, Microsporidia). It has been hypothesized that some genome expansions observed in fungi result as an adaptation to their parasitic lifestyle, with obligate parasites, necessarily with low population size, having greatly expanded genomes. Exactly the opposite of what occur in bacteria, for which obligate symbiosis/pathogenicity leads to genome reduction.

Despite the causes that underline the process, mechanisms that bring to expansions or reduction of genetic repertoire can be very different, and can occur at different levels, i.e., modifications can occur at a genome-wide level or involve limited regions of the genome or even particular gene family or single genes. Genetic variation includes single nucleotide substitutions, insertion/deletions, or larger genetic changes like chromosomal rearrangements, that have low impact on genome size.

Genome Contraction

The reduction of whole genome is not a common event in fungi. Genome reduction has been observed in lower fungi, like in some obligate parasitic fungi of the genera Microsporidia, that have little genomes within the range of 2–6 Mb (Stajich, 2017). Gene family contraction and gene loss have contributed to the evolution of fungal genomes. Gene family contractions have been observed for example in the plant pathogen *Colletotrichum* (Glomerellales; Sordariomycetes) and are associated with host range contractions suggesting that host specificity may be a result of gene losses (Stajich, 2017). Also, in case of host jumps to distant species a subset of the effector repertoire could become obsolete, indeed in the genome of the smut fungus *Melanopsichium pennsylvanicum* that evolved from a grass pathogen to a dicot one, effector gene deletion appears to be rampant (Sharma *et al.*, 2014).

Genome Expansion

Genome expansion can occur for:

- (1) Dispersal and increased number of transposable elements (TE);
- (2) Duplication (Whole Genome Duplication, WGD);
- (3) Acquisition of new genetic material via hybridization or Horizontal Gene Transfer (HGT).

Transposable elements (TEs) and effector evolution

The transposable elements (TE) are mobile genetic units able to move in a genome. In 2007 Wicker *et al.* (2007), proposed a unified system for the eukaryotic TEs classification: two main classes depending on their transposition intermediate, class I (retrotransposons), that transpose using RNA intermediate, with a “copy and paste” mechanism, and class II that transpose directly from DNA to DNA. The class I group is split into 5 orders based on their insertion mechanism: (1) LTRs (Long Terminal Repeats), involved in retrotranscription and integration into new genomic location; (2) LINEs (Long Interspersed Nuclear Elements) including genes for RNA packaging and retrotranscription; (3) SINEs (Short interspersed Nuclear Elements), non-autonomous elements, their transposition often depends on the LINEs; (4) DIRS (*Dictyostelium* Intermediate Repeat Sequence), whose

mechanism of replication is not yet well known; (5) PLEs (PENELOPE like elements), coding for reverse transcriptases and endonucleases. The class II group is divided in the Subclass I, to which belong transposons containing a transposase gene flanked by two Terminal Inverted Repeats (TIRs order) using a “cut-and-paste” mechanism, and the Subclass II, using other mechanisms of transposition, not well known yet (Helitrons and Maverick orders). TEs vary in number and in size, and comprise 3%–20% of the sequenced genome of most fungi. In the phytopathogen *Blumeria graminis*, 85% of the genome, estimated at 174 Mb, includes TEs (Parlange *et al.*, 2011). In the last years the massive genome sequencing of an increasing number of species together with comparative genomics and transcriptomic analysis have led to better understand the mobilome impact on gene expression and genome evolution. In 2019 a systematic, Kingdom wide study concerning mobile elements was carried out analyzing genomic location of TEs in 625 publicly available fungal genomes showing that animal-related and pathogenic fungi have more TEs inserted into genes than fungi with other lifestyles (Muszewska *et al.*, 2019). The recent genomic data of fungal plant pathogens indicate that some of them have drastically expanded genomes, mostly due to massive invasion of TEs. In phytopathogens, TEs represents the major contributor of genetic variability, through chromosomal rearrangements, altered gene expression, gene mutation, deletion and expansion. Thanks to the recent advances in third generation sequencing technology, allowing long-reads sequences and good genome assembly, it was possible to better understand the role of transposable elements in the fungal pathogen genome evolution. It is now well known that they contribute in the evolution of genes involved in plant/pathogen interaction (Seidl and Thomma, 2017). The continuous co-evolution of host and pathogen requires a strong genome plasticity enabling a fast adaptation potential. It has been observed that many TEs are located in genomic compartments enriched in repetitive sequences and transposable elements (Razali *et al.*, 2019; Raffaele and Kamoun, 2012; Seidl and Thomma, 2017) and they are often physically associated to effector genes of many plant pathogens. These observations led to the formulation of the two-speed genome theory according to which many filamentous plant pathogens have a bipartite genomes architecture (Dong *et al.*, 2015), which will be discussed later in this chapter. The physical association between TEs and effectors clearly shows that transposable elements contribute to microbial adaptation in response to plant by establishing genetic variability in effector-rich regions (Raffaele and Kamoun, 2012). A lot of studies support these findings. In *Magnaporthe oryzae*-rice pathosystem, the *Avr-Pita* effector of the fungus, recognized by the *Pita* immune receptor in rice, shows a gene-for-gene relationship with the resistance genes in its host. This effector resides in a sub-telomeric region and is flanked by transposable elements. This location enables a fast diversification of the gene, by point mutations and genomic instability (deletion or insertion, gene translocation), mediated by TEs, allowing the fungus to overcome *Pita*-mediated resistance. The insertion of a transposable element (POT3) in the *Avr-Pita* promoter region results in gain of virulence of the pathogen (Kang *et al.*, 2001; Okagaki *et al.*, 2016).

Similar TE-mediated evolution of effector genes was observed in different well studied plant/fungi pathogenic interactions; in the wheat pathogen *Zymoseptoria tritici*, a population genomic analysis showed that an effector gene located close to a transposable element cluster was lost multiple times from the population, due to extensive chromosomal rearrangements driven by TEs, to avoid recognition by the plant immune receptor (Hartmann *et al.*, 2017). The genome analysis of the phytopathogenic ascomycete *Leptosphaeria maculans* “brassicae” (Lmb) has shown the presence adenine and thymine -rich blocks, (referred as AT isochors), enriched in TEs and effector genes: these particular regions are subject to repeat-induced point mutation (RIP), a fungal defense mechanism against transposable elements that actively induces point mutations in duplicated sequences, leading to high levels of AT (Rouxel *et al.*, 2011). The RIP mechanism can occasionally overrun the repeated region into adjacent effector genes, resulting in a rapid diversification of them. Comparative genomics between *Leptosphaeria* species have revealed a recent TE expansion in the genome of the pathotype *brassicae* that has promoted chromosomal rearrangements, resulting in the fungus speciation, and the active role of TEs to translocate effector genes within AT isochores of the genome, leading to a faster adaptation to selection pressure (Grandaubert *et al.*, 2014).

The evidence of avirulence effector genes in *L. maculans* in the plastic genomic regions represents an outstanding example of how diversification and evolution of effector genes in fungal plant pathogens allow a faster adaptation to host resistance genes. However, escaping resistance gene recognition could also have a cost in terms of loss of individual effectors, which is overcome by the presence of a large plethora of candidate effector genes, as revealed by the genome sequencing of more and more filamentous plant pathogens. The picture in the model phytopathogen *L. maculans* is complicated by the recent identification of some effector genes in *L. maculans* core genome, which were involved in systemic host colonization. Only the release of R genes in commercial plant varieties and the following population analysis will contribute the understanding of effector role in *L. maculans* (Rouxel and Balesdent, 2017).

The structural rearrangements of the genome mediated by TEs was deeply analyzed also in the soil-borne vascular wilt pathogen *Verticillium dahliae*: these chromosomal reshuffling establish highly dynamic lineage-specific (LS) genomic regions that act as a source for genetic variation (de Jonge *et al.*, 2013). Such LS regions are enriched in retrotransposons and other repetitive sequence elements, and in *planta*-expressed effector genes. A comparative genomic analysis between two *V. dahliae* strains has shown that TEs are enriched near rearrangement breakpoints and play a role in chromosomal rearrangements through homology-based recombination and erroneous double-strand repair (Faino *et al.*, 2016). Moreover, while the majority of TEs in *V. dahliae* is silent, the transcriptional activity of TEs, assessed by in vitro RNA-seq data analysis, was observed in LS regions. The relative age of TEs was estimated based on sequence divergence from a consensus sequence and a big amount of “younger” TEs resides in LS regions, whereas the majority of “older” TEs is localized in the core genome. This means that younger TEs, contrary to the older ones, tend to be transcriptionally active (Faino *et al.*, 2016).

The evolution potential mediated by TEs has been proposed also for mechanisms of recombination alternative to sexual reproduction, in the fungal pathogen *Pyrenochaeta lycopersici* (Dal Molin *et al.*, 2018): the genome assembly of this soilborne

pathogen, obtained by using long-read Single Molecule Real-Time sequencing technology (PacBio), allowed to read a fraction of repetitive sequences representing 30% of the total bases in which 15 TE super families were identified. The association of putative protein-coding genes with TEs was investigated, based on the physical association on the genomic sequence: 42 predicted heterokaryon incompatibility (HET) protein-coding genes were found in proximity of predicted TEs, suggesting the putative need for this fungus, which lost the ability of sexual reproduction, to increase the evolution of these genes which contribute to genetic recombination.

The control of the activity and the spread of TEs represents a key factor in the evolution of a fungal microbe. Only thanks to fine regulation mechanisms each species developed an evolutionary compromise in which the fitness deficit due to the deleterious effects of a strong TEs expansion (genome “obesity”, deleterious genic and structural mutations) is counterbalanced by the selective advantage conferred by enhanced genome plasticity. Generally, the transposable element activity is regulated through epigenetic control mechanisms such as DNA methylation or histone modifications, targeted mutagenesis (RIP), and small RNA interference. The epigenetic regulation within a species population was reported to be variable and environmentally influenced; in particular environmental stresses have been associated to epigenetic de-repression of TEs (Fouché *et al.*, 2020). The plant pathogens represent an excellent model of study to explore TEs regulation dynamics as in the infection process the pathogen must face up a number of severe stresses; the expression of effectors is often regulated by de-repression of facultative heterochromatin (Soyer *et al.*, 2015; Soyer *et al.*, 2019). As discussed above, these regions of heterochromatin encoding effectors, overlap with TEs and consequently de-repression of TEs is associated with the expression of effectors.

Genome evolution in *Pyrenophora teres*, a necrotrophic pathogen of barley, is also featured by the insertion and expansion of TEs, the process is particularly evident in *P. teres f. teres* (PTT) which is characterized by a higher fraction of repetitive elements and a younger transposon mobility than *P. teres f. maculata* (PTM). Virulence of isolates is associated to fungal growth and different effector production and expression, about two hundred effectors were estimated to be produced by PTT isolates and most of the coding genes were localized in subtelomeric regions rich in repetitive elements which confer higher polymorphic trait development. Moreover, the fusion between chromosome 1 and 2 has been detected in one PTT isolate, this is supposed to be a recent event and was also detected in one *Pyrenophora tritici-repentis* isolate, leading to the hypothesis that chromosome fusion could be a common trait of *Pyrenophora* genus (Syme *et al.*, 2018; Wyatt *et al.*, 2020; Clare *et al.*, 2020).

In a recent transcriptomic study, TEs expression pathways were analyzed in four strains of the wheat pathogen *Zymoseptoria tritici* (Fouché *et al.*, 2020). After exposing the strains to nutrient starvation and host infection stress, surprisingly the two distinct conditions induced different expression profiles of TEs. In particular, the most highly expressed TEs, including TIR and Gypsy elements, show highly distinct de-repression across stress conditions. The genomic location of TEs was a major predictor of de-repression mechanisms during stress. Gene expression profiles under stress varied significantly depending on the proximity to the closest TEs: in other words, effector genes co-localized with TEs are subjected to the epigenetic upregulation during the period of infection.

Whole genome duplication (WGD) and polyploidy

Generally, duplication can favor evolution of new genes, allowing the original gene to maintain continuity in the gene product and in cell function, while providing a paralog that could “experiment” diverging in product and function (Kohn, 2005). Duplication can occur by unbalanced meiotic recombination and TE-mediated.

Analysis of filamentous plant pathogen genomes showed that different species undergo or have undergone to Whole Genome Duplication (WGD). A WGD event can occur as autopolyploidy by doubling the copy number of each chromosome (for example by an asymmetric meiosis) or as allopolyploidy by hybridization of two different species. (We will afford the former here and the latter later on in the chapter). WGD is usually followed by diploidization because polyploid organisms show a general instability with different meiotic defects such as abnormal chromosomal disjunction or atypical meiotic timing and topology (genome instability of polyploids can also be observed during mitosis) (Albertin and Marullo, 2012). Diploidization is the process by which a polyploid organism returns to a more stable diploid mode of chromosome pairing and can involve different mechanisms. Processes that contribute to diploidization include sub-functionalization and/or neo-functionalization causing differentiation between redundant gene copies and/or large-scale chromosomal rearrangements such as translocations, chromosome loss, telomere-to-telomere fusion between chromosomes.

Transposable elements (TEs) and other repeated sequences are traditionally involved in fungi post-polyploid evolution. Following a WGD event, ectopic recombination between TE elements or other repeated sequences can occur resulting in reciprocal translocations in chromosomes. Other well-known repeated sequences associated with genome restructuring in polyploids are the clusters of ribosomal DNA (rDNA) which are known to undergo to concerted evolution that is partial or complete homogenization of their rDNA. Genetic diversification in polyploids may involve smaller sequences and encompass limited duplication of single genes or gene families and/or gene loss. Hence, also in filamentous plant pathogens as in plants and animals, WGD is associated with long- or short-term structural, functional and phenotypical diversification.

From a functional viewpoint, one plus one does not equal two in polyploids. Many plant- and animal-duplicated genomes transgress the additivity hypothesis (predicting mid-parent relative expression), the fewer cases observed in fungi also display non-additive expression. Functional changes may be related to the structural diversification. Dosage compensation, a process by which genes duplicated by polyploidy or aneuploidy show diploid-like expression, has been observed in the functional evolution of *Saccharomyces pastorianus* (Albertin and Marullo, 2012). Moreover, epigenetic regulation of gene expression is possibly involved in fungi, as it has been observed for plants.

In conclusion, polyploidization triggers several structural and/or functional changes that are assumed to favor phenotypic diversification and thus facilitate further evolution and adaptation in filamentous plant pathogens.

It must be said that variations in genome content may also be associated with life cycle or cellular differentiation, this kind of phenomena are defined as somatic polyploidy (or endopolyploidy) rather than actual polyploidy. Several environmental factors have been shown to induce variation of genome content and chromosomal complement in various fungal species, such as heat shock, saline stress, fungicides treatments, or host–pathogen interactions.

Evidences of recent or ancient WGD events have been observed in Blastocladiomycota, Glomeromycota, Basidiomycota and also in the largest fungi phylum of Ascomycota, in which, beside the well-described *Saccharomyces* genus, there are also pathogenic species like *Botrytis* (reviewed in Albertin and Marullo, 2012).

In oomycetes, both autopolyploids and allopolyploids (see below) are known. For example, *Phytophthora megacarya* has an exceptionally large genome (222 Mbp) due to a recent expansion by whole-genome duplication (WGD) followed by diploidization (paleopolyploids). WGD and a dramatic transposable element associated expansion of a few gene families led to this exceptionally large genome and transcriptome and to the diversification of virulence-related genes including secreted RXLR effectors (characterized by the motif: Arg-X-Leu-Arg, where X is any amino acid). Overall, *P. megacarya* has an exceptional effector content of 1382 RXLR effectors (Morales-Cruz *et al.*, 2020).

Lateral DNA transfer and hybridization: Mechanisms of gene exchange between species

Gene exchange between species, through hybridization and Lateral DNA Transfer (LDT), represents another mechanism for fast evolution of filamentous plant pathogens. LDT includes Horizontal Gene Transfer (HGT) and Horizontal Chromosome Transfer (HCT). Actually, the broad occurrence of gene exchange observed among these organisms challenges our species concepts in the Kingdom Fungi and Oomycetes. Comparative genome studies have shown that fungal and oomycetes genomes can evolve very rapidly, evidencing high levels of genomic variation (distinct genome composition, sequence divergence, distinct chromosome organization). Genomic variation has in particular been studied among pathogenic species for which rapid evolution confers a main challenge for disease control.

Horizontal gene transfer (HGT) and horizontal chromosome transfer (HCT)

In fungi, as well as in bacteria, is well known the involvement of LDT in the genomic evolution process. Referring to pathogenic fungal species, HGT represents a fast and functional source of variability. By introducing exogenous genes, HGT gives selective advantages, such as the ability to become pathogenic to a specific host. HGT is defined as the stable transfer of genetic material between individuals, however, this definition is not that simple because is not due to a specific biological process (Doolittle, 1999). HGT excludes transfer through meiotic recombination or mitotic processes, such as parasexual recombination, which are known as vertical gene transfer (Rosewich and Kistler, 2000). In bacteria there are different specific biological processes as conjugation, transformation, or transduction involved in HGT (Davison, 1999).

An increasing number of genomic studies are highlighting and identifying the exogenous DNA sequences, distinguishing when the DNAs come from a more or less related species (Mehrabi *et al.*, 2011). Indeed, HGT may occurred recently in the evolutionary process of a species.

Despite the genomics era pointed up evidence for HGT occurring among prokaryotes and from prokaryotes to eukaryotes or vice versa, there are few occurrences of documented HGT among eukaryotes or even HGT of an entire cluster of genes (Khaldi *et al.*, 2008). In the last two decades, the number of published works on HGT in fungi has increased significantly (Fig. 1). Although there are little experimental evidences indicating HGT as inter or intra-species process, HGT was theorized and then demonstrated in a few examples.

In plant pathogenic fungi, the genes responsible for the synthesis of specific metabolic pathways, such as secondary metabolites involved in host/pathogen interactions or communication between organisms, are usually coordinately regulated and located together within gene clusters. HGT of metabolic pathway clusters increases the likelihood that the co-mobilized genes could give an adaptive advantage in certain ecological niches. These clusters can be maintained by positive selection in those environments (Rosewich and Kistler, 2000).

Many filamentous fungi genus, such as *Fusarium*, are capable to produce toxic secondary metabolites, also known as mycotoxins. One of the most studied family of mycotoxins is that of fumonisins, which can accumulate on kernels in field and during harvest and can be dangerous for animals or for human health when they are found on feed or food (Leslie and Summerell, 2006; Munkvold and Desjardins, 1997; Nelson *et al.*, 1991). Fumonisin are classified into more than 90 analogs divided in A, B, C and P-series (Proctor *et al.*, 2013). Although most of the known *Fusaria* species able to produce fumonisins, predominantly B fumonisin, are included in the *Fusarium fujikuroi* species complex (FFSC), there are some rare exceptions, such as a C fumonisin producing isolate of *Fusarium oxysporum*, a species closely related to FFSC (Seo *et al.*, 1996; Sewram *et al.*, 2005). Often, fumonisin biosynthetic genes (FUM) can be found in gene clusters. FUM is a linear polyketide-derived backbone type cluster organized in 17 contiguous genes in *Fusarium verticillioides* and *Fusarium proliferatum* genomes (Khaldi and Wolfe, 2011; Proctor *et al.*, 2013). The FUM cluster includes genes such as a polyketide synthase (PKS), a fatty acyl-CoA synthase (FAS) and cytochrome P450 monooxygenase (CYP) that contribute to the fumonisins biosynthesis, as well as two transport proteins, and is regulated by a Zn₂Cys6 DNA-binding protein transcription factor (Susca *et al.*, 2014). FUM genes are apparent duplicates of conserved genes in Sordariomycetes fungal class. Two scenarios could be involved in FUM cluster evolution in *F. verticillioides*: (1) the FUM cluster could be the result of horizontal cluster transfer into an ancestor of *F. verticillioides*, (2) the FUM cluster may have been recently assembled after gene duplication in an ancestor of *F. verticillioides* (Khaldi and Wolfe, 2011). FUM has been described in *F. proliferatum* and *F. verticillioides*, both species included in the FFSC, in *F. oxysporum* and in the different genus and distantly related

Fig. 1 Publications on Horizontal Gene Transfer in fungi. Number of publications per year, since 1984–2019. <https://pubmed.ncbi.nlm.nih.gov/?term=hgt+fungi&sort=date&size=200>.

fungus *Aspergillus niger* (Proctor *et al.*, 2013). The *F. oxysporum* strain O-1890 is a known C fumonisins producer, too. Moreover, genomic analyses of FUM cluster in *F. verticillioides*, *F. proliferatum* and *F. oxysporum* showed different genomic locations in the three species, though *F. oxysporum* has different FUM cluster flanking DNA sequences (Proctor *et al.*, 2008).

The homolog of the *Fusarium* FUM cluster present in the *A. niger* genome might represent an interesting example of putative HGT. The *A. niger* cluster includes 11 FUM homologs and also includes a short-chain dehydrogenase gene whose function has not been reported (Baker, 2006). The *A. niger* cluster lacks different FUM genes orthologues (FUM11, FUM12, FUM16, FUM17 and FUM18) and the FUM genes are different; moreover, in the *A. niger* cluster, there are at least three genes that lack in the FUM *Fusarium* cluster. However, no difference in fumonisins structural diversity was reported in *A. niger* fumonisins (Khaldi and Wolfe, 2011). Phylogenetic analysis, comparing different *Fusarium* species, suggests the occurrence of a putative HGT between *A. niger* and a *Fusarium* ancestor prior to the divergence of *F. verticillioides* and *F. oxysporum*. Moreover, the phylogenetic analysis of the FUM clusters, both in *Fusarium* and *Aspergillus*, showed that the HGT event probably occurred from Sordariomycetes to *A. niger*, or his ancestor, rather than the opposite (Khaldi and Wolfe, 2011).

Another very important example of HGT as inter species process, is that occurred between *Stagonospora nodorum* and *P. tritici-repentis*, reported by Friesen *et al.* (2006). They showed evidence of the transfer of a gene encoding a host-selective toxin, ToxA, the gene was transferred from *S. nodorum* to *P. tritici-repentis* conferring to this last pathogen the virulence on wheat and suggesting that this transfer occurred just before 1941. In fact, in that year *P. tritici-repentis* was reported as the cause of the first serious outbreak of leaf spotting on wheat in the USA (Friesen *et al.*, 2006).

Finally, based on sequence homology analysis, in oomycetes some genes related to pathogenicity are hypothesized to have been acquired from donor genomes of fungi by HGT, suggesting a Kingdom-to-Kingdom transfer (Savory *et al.*, 2015).

Another type of horizontal transfer event is represented by the Horizontal Chromosome Transfer (HCT). HCT event assumes the transfer of a “supernumerary chromosome” (SC), a small accessory chromosome, generally less than 2 Mb, characterized by gene density lower than that of the ‘core’ chromosomes, none or at least few housekeeping genes and rich of repeated elements (Bertazzoni *et al.*, 2018). SCs are often meiotically unstable, i.e., they can be lost during meiotic division processes (Covert, 1998). It has been observed, in different *F. oxysporum* f. sp. *lycopersici* (FOL) isolates, that the size of the “core” chromosomes is well-preserved; nevertheless, the SCs genes content is variable. All FOL analyzed isolates show different profiles of presence/absence of genes encoding virulence effectors secreted in the host xylem (SIX), the presence of these genes can be used to predict host specificity (van Dam *et al.*, 2016; Williams *et al.*, 2016). It has also showed that these SCs may include ‘lineage specific’ regions (LS) or sequences typical of a single species.

In 2010, Ma and colleagues demonstrated the involvement of HCT by the transfer of pathogenicity chromosomes in *Fusarium*. The mobilization of SCs can transfer an entire set of genes leading to host compatibility to a non-pathogenic strain. Small proteins, secreted by FOL during the interaction with tomato, such as Six1 (Avr3) and Six3 (Avr2), are involved in virulence. These proteins

are coded by genes located on chromosome 14, one of the FOL LS chromosomes. Moreover, genome analysis revealed at least other three small in planta-secreted proteins on chromosome 14 (SIX5, SIX6 and SIX7). These genes are all conserved in pathogenic strains of tomato, but are not present in non-pathogenic strains. Ma and colleagues demonstrated that LS chromosome 14 was responsible for FOL pathogenicity and that HCT of this chromosome between strains explains its presence in several clonal polyphyletic lineages within the *F. oxysporum* species complex, but the absence in other lineages (Ma *et al.*, 2010).

HCT is also known to be involved in the evolutionary process of *Alternaria alternata* pathotypes; indeed, specific toxin coding genes reside on LS chromosomes. Protoplast fusions of two pathotypes yield LS chromosomes from both parental hybrids, supporting the HCT hypothesis (Akagi *et al.*, 2009).

Hybridization through sexual mating and by vegetative fusion of fungal hyphae

Hybridization can result in the formation of new species that occupy new ecological niche, or the hybrid can be a transient stage that can stabilize in different way, for example by backcrosses with the parental species, leaving only fragments of introgressed sequences in the genome (Feurtey and Stukenbrock, 2018). Hybridization in filamentous plant pathogens can occur by sexual mating or by fusion of vegetative cells of individuals belonging to different species.

Sexual mating between heterospecific individuals is prevented by reproductive barriers, but it can occasionally occur and give rise to hybrid individuals. Across all fungal phyla, hybridization is likely the most direct route to sympatric speciation, although there are as yet only a few examples of hybridization adequately supported by evidence. It is more common the emergence of a new lineage by hybridization of different host-specialized lineages or *formae speciales* (f.s.) within the same species, like what it was observed in the cereal pathogen *Blumeria graminis* comprising different f.s. on rye, barley and wheat. Recently, a new powdery mildew lineage emerged on the hybrid crop species triticale (x *Triticosecale*). *Blumeria graminis* f. sp. *triticales* comprises a mosaic of segments with high sequence similarity to either the rye or the wheat pathogen, *B. graminis* f.sp. *secalis* and *B. graminis* f.sp. *tritici* respectively. Detailed analyses of the polymorphism pattern between the three *formae speciales* revealed a very recent origin of *B. graminis* f. sp. *triticales* by a hybridization event of *B. graminis* f. sp. *secalis* and *B. graminis* f. sp. *tritici* followed by a few backcrosses to *B. graminis* f. sp. *tritici* (Feurtey and Stukenbrock, 2018).

Recent allopolyploid hybrids have, however, been identified in diverse genera of non-plant pathogens like several *Neotyphodium* species, symbiotic endophytes of grasses, and several *Saccharomyces* species empirically selected for brewing; but also plant pathogen like *Botrytis allii* the agent of gray mold neck rot of onion and garlic (reviewed in Giraud *et al.*, 2008).

Some hybrids have the ploidy level identical to that of their parents, they are referred to as homoploids, and they are characterized by a broad heterozygosity and by the fact that they are not reproductively isolated from their parents. A well-described case of homoploid speciation is that of the rust *Melampsora columbiana* that emerged from hybridization of *M. medusa*, parasite of *Populus deltoides*, and *M. occidentalis*, parasite of *P. trichocarpa*. This hybrid emerged in 1997 when a poplar hybrid resistant to the two parental rust species was widely grown in California, the hybrid rust being able to infect the hybrid poplar. In this case, the homoploid hybrid clearly had a novel ecological niche, a new host (Newcombe *et al.*, 2000).

Unlike fungi, oomycetes are diploid and over the past decade it has become apparent that intraspecific hybridization is a common occurrence in this class. Actually, interspecific hybridizations are increasingly recognized as a driving evolutionary force in the genus *Phytophthora* facilitating adaptation to new environments and expansion of host ranges or host jumps due to accelerated pathogen evolution.

To date, an average of 140 *Phytophthora* species have been described, but the true global diversity of the genus *Phytophthora* has been estimated as 400 ± 200 extant species (Brasier, 2007). This is probably due to the huge genome plasticity that allow generation of diversity within this genus. First source of variability of course is sexual recombination: oomycetes can be heterothallic, in which reproduction can occur only between two different but compatible individuals or homothallic, which are capable of sexual reproduction from a single organism. Other sources of variability in oomycetes are based on transposons, gene duplication, asymmetric recombination, horizontal transfer and, in particular, hybridization and polyploidy (common in the genus *Phytophthora*). The lack of heterozygous nucleotides in their maternally inherited mitochondrial genes, a feature common to all known *Phytophthora* hybrids, strongly suggests that they originated from sexual hybridization rather than somatic fusion. Many of these hybrids exhibit polyploidy. The progeny of a single hybridization event can follow different evolutionary paths, in fact hybrid isolates from the same event can show large variations in DNA content indicating different levels of ploidy: polyploid (probably tetraploid) isolates can be present together with diploid isolates or diploid/polyploid heterokaryons. It is now clear that these hybridization events and polyploidy play an important role in host adaptation and speciation of *Phytophthora* pathogens. For example, the host-specific pathogen *P. × alni* is the product of multiple interspecific hybridization events between unknown parental species that formed *P. × multiformis* which then hybridized with *P. uniformis*. *Phytophthora × alni* is significantly more widespread and aggressive to *Alnus* spp. than its parents, causing epidemic mortality of *Alnus* trees across Europe (Ioos *et al.* 2006). *Phytophthora × alni* and *P. × multiformis* are recent hybrids in a nascent state, characterized by unusually high developmental instabilities and oospore abortion rates. In contrast, the functional heterothallic breeding system and lack of developmental instabilities suggest that *P. × cambivora* already went through the process of stabilization and homogenization and, hence, is not of recent origin. This conclusion is also supported by the fact that the original description as *Blepharospora cambivora* was published one century ago. This means that some hybrids could represent transient hybrid clones but the ones that demonstrated higher fitness could become stable evolutionary lineages.

Most of these new hybrid taxa are apparently a by-product of globalization, with human activities associated with nurseries, ornamental gardens, horticulture and agriculture. These are environments where infected germplasm and other material (such as

soil) from disparate origins are bought together, providing a natural laboratory for the formation and selection of hybrids. Also, natural ecosystems, like tropical ecosystems of Southeast Asia, characterized by the ecological diversity and high degree of plant species endemism have been shown to favor hybridization events.

Despite vegetative incompatibility mechanisms in all filamentous plant pathogens, fusion of hyphae of heterospecific individuals can occasionally occur. Interspecific vegetative fusion can give rise to new lineages that contain the entire genomes of both parental species. This is the case of the ascomycete fungus *Verticillium longisporum* which is diploid but arose from hybridization of haploid ancestors. Population genetic data provide evidence that *V. longisporum* is the product of more than one hybridization event between closely related *Verticillium* species. *Verticillium longisporum* predominantly propagates by asexual reproduction, and hyphal fusion followed by karyogamy is therefore the most plausible hybridization scenario (Feurtey and Stukenbrock, 2018). *Fusarium oxysporum* is another example of the adaptive advantage of hyphal fusion followed by the exchange of genetic material in asexual species. As mentioned above, in this species genomic variability can be achieved by lateral DNA transfer.

Rapid Evolution of Virulence Associated Genes: One, Two, Multi-Speed Genomes

The “two-speed genome” model describes a genome architecture typical of filamentous plant pathogens in which genomes have a bipartite structure, with gene sparse compartments enriched in repetitive sequences and transposable elements showing higher evolutionary rates compared to more conserved gene-dense regions (“core” genome) enriched for housekeeping genes. These repeat-rich regions contain large repertoire of genes coding for effectors involved in virulence and serve as a cradle for adaptive evolution (Dong *et al.*, 2015).

Remarkably, this unusual genome architecture has evolved in independent phylogenetic lineages of filamentous plant pathogens, fungi and oomycetes belonging to different Kingdoms. The distinctive two-speed genome architecture, with the effector genes populating the more rapidly evolving sections of the genome, is associated to the rapid evolutionary *tempo* of effector genes and gives to the lineages that possess it a clear advantage in the antagonistic co-evolutionary conflict with plants. The evolutionary success of filamentous plant pathogens is due to the ability to rapidly overcome plant immunity, adapt to resistant varieties and occasionally jump to new host species. A more adaptable genome prevents them to succumb as their hosts develop full resistance or become extinct.

Mechanisms of mutations

The repeat-rich, gene poor genome compartments show higher evolutionary rates because they represent hot spots for duplication, deletion and symmetric and/or asymmetric recombination; moreover, high transposase activity is observed, altogether resulting in accelerated evolution through increased structural variation. However, also other mechanisms are involved. Beside normal mutations, in some ascomycete fungi, close proximity of effector genes to degenerated transposons can result in increased levels of local mutagenesis through RIP mutations. (No RIP-like mechanism has been demonstrated in *Phytophthora* species or other oomycetes). Moreover, epigenetic silencing can also affect effector genes, but it still to be shown that these genome compartments accelerated this phenomenon. Proximity to transposons may also facilitate HGT. Of course, shifting or jumping from host to another, is expected to represent a powerful selective pressure on these genetic variants. The change of plant cellular environments dramatically impacts effector evolution, likely the accumulation of mutations can improve or expand effector activity (Dong *et al.*, 2015).

The genome of the oomycete *Phytophthora infestans*, the potato late blight pathogen, and its close relatives *Phytophthora*, represent the prototypes of this two-speed genome compartmentalization. In these pathogens, effector genes can be readily annotated in genome sequences because they contain signal peptides followed by conserved motifs. This is the case of the family effector gene called Crinklers (CRN) or RXLR in *Phytophthora* and downy mildews. In these genomes fast-evolving genes coding for these effectors mainly reside in gene-sparse regions.

However, with more filamentous phytopathogen genomes being sequenced, it is becoming clear that there are rapidly evolving phytopathogens that lack either some or all of the aforementioned characteristics, indicating that there are more modes of genomic organization to obtain different speeds in evolution. In this context, Frantzeskakis *et al.* (2019) recently proposed a one-speed (one-compartment) and a multi-speed (multi-compartment) genome organization, as alternative to the two-speed genome model. In one-speed genome rapid evolution of effector genes is not constraint to certain compartments: these genomes are characterized by over-proliferation of TEs (due to the loss of RIP), equal distribution of TEs and absence of genomic compartmentalization. In these genomes, rapid evolution is supposed to be enhanced by extensive copy-number variation and/or heterozygosity. On the other side, genomes containing accessory chromosomes carrying rapidly evolving effector genes, typical of *F. oxysporum* as an example, could be described as multi-speed genomes, since they seem to possess three speed levels including core, pseudo-core (core chromosomes displaying presence/absence polymorphism) and lineage-specific chromosomes.

Beside further definitions, filamentous plant pathogen genomes surely need rapid evolution of virulence-associated genes to successfully cope in the arm race with the plant and they do not put limit to the different ways to obtain it.

Introduction of Alien Pests in New Environments: *Phytophthora Ramorum*, as Example of Genetic Diversification in Asexually Propagated Filamentous Pathogens

Alien species are often successful invaders in new environments, despite the introduction of a few isolates with a reduced genetic pool. This is called the “genetic paradox” of invasion.

Small populations or clones can reproduce clonally with the advantage to cause a rapid increase and dispersal of a population in a temporal/geographic sense (epidemic), frequently accompanied by the elimination of sexual reproduction due to the absence of one mating type. However, in this way pathogen populations lose genetic diversity and without adaptability and plasticity enabled through genetic recombination invaders will not be able to cope with long-term change in host resistance or environmental changes, and epidemic pathogens will succumb. Successful invasive alien pathogens show instead high genotypic diversity that increase their potential for adaptation, explain their success in invasion and long-term persistence. This genotypic diversity is due to a parasexual life-cycle characterized by mitotic recombination.

Phytophthora ramorum has a wide host range and infects over 100 species of plants, both wild and ornamental, causing leaf lesions and/or branch dieback. It is an invasive pathogen that, despite being limited to asexual reproduction and having a small effective population size, is spreading extensively in Europe and North America, causing heavy mortality on ecologically and economically valuable forest trees such as larch and oak species.

The pathogen comprises four divergent clonal lineages, (NA1, NA2, EU1, EU2) that have spread in the United States, Europe, and Canada. The lineages differ in morphology and aggressiveness and, despite their presumed clonality, exhibit considerable intra-lineage phenotypic (genetic) variation.

Long term studies (reviewed in Dale *et al.*, 2019) have shown that asexual lineages of *P. ramorum* can evolve by mitotic recombination (MR) and rapidly evolving non-core genome. The latter, characterized by rapid evolution of effector genes in gene-sparse regions enriched in repetitive sequences and transposable elements (TEs), has been already discussed in the chapter on two-speed genomes. MR is one mechanism that can generate genotypic diversity, uncovers beneficial mutations, and increases the potential for adaptation. It is caused by crossing over during mitosis at specific chromosomal breakpoints along the genomes of these *P. ramorum* lineages. All sites after the breakpoint were converted to homozygosity for either the reference or alternate allele relative to the reference genome, resulting in extensive runs of homozygosity (ROH, also known as loss of heterozygosity [LOH]) regions, covering large portions of or entire scaffolds. Conversion of genomic regions to homozygosity may result in the expression of new or recessive alleles and can improve the efficiency of selection on both beneficial and deleterious alleles (Dale *et al.*, 2019). TEs and low gene density are associated with mitotic recombination. The prevalence of MR in *Phytophthora* species suggests it is a salient characteristic of the *Phytophthora* genetic system. MR may therefore be important in enhancing the adaptability of introduced asexual *Phytophthora* species and contribute, along with a rapidly evolving non-core genome and a strong selective pressure, to the initial invasion “success” but also in the long-term adaptation to environmental changes, such as loss of susceptible hosts and the emergence of parasites or competitors.

Conclusions

Evolution of virulence and adaptation in filamentous phytopathogens are ruled by genome plasticity and include different mechanisms: gene duplication, deletions, copy number variation, heterozygosity, loss or acquisition of dispensable chromosomes, chromatin rearrangements. The increasing availability of complete and high-quality genomes, will contribute to understand the frequency of each event of gene evolution, the origin of the genomic architectures observed and whether they are the results of selection pressure or due to chance of genetic drift. The complete genomic datasets available for numerous filamentous pathogens also indicate that closely related species can follow different genomic evolution pathways. This is the case of *F. oxysporum*, where the accessory and pseudo-core chromosomes provide potentially additional genome plasticity, while in *F. graminearum* have not been found dispensable chromosomes, and a small fraction of TEs is present. Another example comes from *Ustilaginales*, where in some species effector genes are clustered in the proximity of TEs, while in other species TE insertion sites are not correlated with effector clusters.

The main tool for increasing the level of genotypic diversity in fungal pathogens is represented by sexual recombination and can influence the virulence spectrum. Knowledge of the mating system of a species is important to be able to differentiate locus-specific effects from genome-wide effects. Several mating-type genes have been cloned from ascomycete fungi and they have proven useful in distinguishing the mating types. Knowledge on the virulence spectrum of a pathogen population and recognition of the risks of changes in the virulence spectrum are essential when breeding crops for disease resistance.

Introduction

There are numerous examples of plant, animal and bacterial viruses that cause severe symptoms of disease (up to death of the host), with considerable socio-economic impacts (Martinelle *et al.*, 2014; Esposito *et al.*, 2005; Vurro *et al.*, 2010). Viruses of fungi, also known as mycoviruses, were described for the first time during 1960s, as pathogens of cultivated mushrooms (Hollings, 1962). Despite their description as disease agents, they often infect their hosts without causing obvious signs of disease and for this reason they are often described as cryptic viruses (Pearson *et al.*, 2009). Like viruses that infect plants, insects and other animals, mycoviruses require the living cells of fungi to replicate (Ikeda *et al.*, 2013). They share some features with other viruses but they also show unique characteristics. Almost all the known mycoviruses lacks an extracellular phase: they are mainly transmitted by hyphal fusion, sexual reproduction or by other mechanisms that require an exchange of cytosolic matter (Chu *et al.*, 2004). Even though, it seems that the restriction of finding a compatible mating isolate for hyphal fusion, and hence virus transmission, occur only during in vitro experiment: in nature the host range of mycoviruses seems to be wider than what expected. For example a virus isolated from *Botrytis porri* was then also found in *B. squamosa* and in *Sclerotinia sclerotiorum* which shared the same ecological niche (Wu *et al.*, 2012). Another similar example was reported for the white rot fungus *Rosellinia necatrix*: in natural environment two incompatible strains were able to exchange viruses between them and also with other fungal species (Yaegashi *et al.*, 2013). The explanation for this phenomenon come from the fact that mycoviruses, as all the other viruses, display a peculiar feature: differently from eukaryotes and prokaryotes which are represented by a single consensus genome sequence, viral genomes are represented by a cloud of closely related mutants termed “viral quasispecies” (Domingo *et al.*, 2012). More in detail, this feature seems to represent an evolutionary advantage, giving to genome variants more chances to adapt to a new environment (which is represented by a new cellular host). The only mycovirus for which an extracellular life-cycle was demonstrated is represented by a DNA mycoviruses which infect *S. sclerotiorum* (Yu *et al.*, 2010). Interestingly, such viruses demonstrated to be infectious when applied extracellularly as purified virus particles. Moreover, the same virus demonstrated also the ability to be transmitted by insects (Liu *et al.*, 2016). In specific, when the mycophagous insect *Lycoriella ingenua* was left feeding on *S. sclerotiorum* infected colonies, it acquired the virus and was then able to infect virus free fungal colonies. In consequence, it seems that transmission in natural environments is more feasible and easily achieved than in axenic condition, also between different species.

Distribution and Phylogeny

Holobiomes is the microbial communities associated with plants or animals, including bacteria, fungi and viruses, that are increasingly recognized as crucial factors influencing host health and fitness (Zilber-Rosenberg and Rosenberg, 2008). Mycoviruses are part of the natural holobiomes and are widespread in all the major taxonomic groups of fungi including pathogenic, saprotrophic and endophytic fungi. For example, one of the most famous case in which a mycovirus play a crucial role for the holobiont adaptation is represented by *Curvularia thermal tolerance virus* (CThTV) (Marquez *et al.*, 2007). In specific, the Marquez and coauthors demonstrated that a mycovirus infecting an endophytic fungus was the keystone which allowed the exploitation of heated soils (up to 65°C) by the tropical panic grass *Dichanthelium lanuginosum*. When they “cured” the fungus, obtaining an isogenic virus-free isolate, its interaction with the plant was unable to induce thermal tolerance. This ground breaking work demonstrated that mycoviruses can play crucial role, providing fundamental ecological services in natural environment. Thanks to such result a new interest for mycoviruses risen up and spurred researchers to look for new mycoviral species in many different environments leading to the description of a number of new viral species. For example, the fungal community inhabiting marine plants (Nerva *et al.*, 2016) and animals (Nerva *et al.*, 2019b) displayed to harbor viruses, as well as endophytic (Marzano and Domier, 2016; Nerva *et al.*, 2019d), pathogenic (Marzano *et al.*, 2016; Donaire *et al.*, 2016; Botella *et al.*, 2015) and symbiotic fungi (e.g., mycorrhizal fungi and fungi associated to lichens) (Neupane *et al.*, 2018; Turina *et al.*, 2018; Petrzik *et al.*, 2019). Thanks to all these works the evolutionary relationship between viral families are now clearer.

The Nobel laureate David Baltimore, in 1971 proposed the modern classification of viruses (Baltimore, 1971): viruses are classified into 7 fundamentally different groups depending on the nature of genome encapsidated into their virions. The central theme of Baltimore system for virus classification is that all viruses must synthesize messenger RNAs (mRNAs) from their genomes, in order to produce proteins and replicate themselves. Despite the presence of 7 distinct groups of viruses, since few years ago the majority of reported mycoviruses displayed a double-stranded RNA (dsRNA) genome, with few reports of positive single-stranded RNA genomes (+ ssRNA). This fact was mainly due to the method used, up to that time, for virus discovery, where the crucial step was the enrichment of dsRNA fraction and then the identification through sequencing (Pearson *et al.*, 2009). For these reasons, Next Generation Sequencing (NGS) applied on total RNA extracted from fungi, or directly from complex matrixes (Al Rwahnih *et al.*, 2011; Marzano and Domier, 2016),

led to the discovery of new classes of mycoviruses. To date, known mycoviruses belong to dsRNA clade, + ssRNA clade, negative single-stranded RNA (-ssRNA) clade and positive circular single-stranded DNA (ssDNA) clade. The latter is represented by *Sclerotinia sclerotiorum hypovirulence-associated DNA virus 1* (SsHADV-1), a member of circular Rep-encoding ssDNA viruses (CRESS DNA) (Zhao *et al.*, 2019), which led to the constitution of a new family named *Genomoviridae* (Krupovic *et al.*, 2016). The genome structure of this family is quite similar to that of *Geminiviridae* (Zerbini *et al.*, 2017), a well-known group of plant viruses, lacking the movement protein indispensable in plant viruses for spreading in their hosts (Deom *et al.*, 1992; Heinlein, 2015).

As previously mentioned, thanks to advent of NGS techniques a number of new viruses were described in both the + ssRNA and the -ssRNA clades. In specific, in the + ssRNA clade there are many viruses belonging to the Tymovirales order which led to the constitution of two new viral families: *Gammaflexiviridae* (Adams *et al.*, 2012) and *Deltaflexiviridae* (Li *et al.*, 2016). In addition to the Tymovirales, many other mycoviruses belonging to the *Virgaviridae* (Adams *et al.*, 2009), *Tombusviridae* (Sit and Lommel, 2001) and other with no obvious phylogenetic placement (Nerva *et al.*, 2016, 2019b; Zhang *et al.*, 2019; Cañizares *et al.*, 2018) were described. Among mycoviral families with a + ssRNA genome, it is worth noting the family *Hypoviridae*. This group of viruses is able to induce a wide fitness reprogramming of the fungal host which lead also to phenotypic and behavioral changes (Rigling *et al.*, 1989; Hillman *et al.*, 1990; Larson *et al.*, 1992; Craven *et al.*, 1993; Zhang *et al.*, 1993; Rigling and Prospero, 2017; Turina and Rostagno, 2007). Finally, the most abundant viruses with + ssRNA genome belongs to *Mitoviridae* and *Narnaviridae* families. These two families host viruses with a very simple genome, which only encode for the RNA-dependent RNA polymerase (RdRP) involved in genome replication. The difference between these two families is that *Mitovirus* species replicate in the mitochondria, as suggested by the name, whereas *Narnavirus* species replicate in the cytosol. A further hint of mitochondrial replication is that in *Mitovirus* genomes tryptophan (Trp or W) is often encoded by the UGA codon (Kitahara *et al.*, 2014). It is worth to note that, in cytosolic ribosomes, UGA is the former codon for translation termination and hence tryptophan is encoded by UGG codon. Further interesting evolutionary theories are also related to these two families as largely discussed in the next paragraph.

Fungal viruses with negative single-stranded genomes are, among mycoviruses, the last discovered group. The first indirect evidence for the presence of this group of viruses was provided in 2013 using a bioinformatics approach (Kondo *et al.*, 2013) on accessible RNAseq experiments in public databases. Then, the following year, it was reported the biological characterization of the first -ssRNA virus replicating in *Sclerotinia sclerotiorum* (Liu *et al.*, 2014). From that moment a number of other viruses belonging to this group were reported, with new member inserted in the Monengavirales, Bunyavirales and Serpentinovirales orders (Nerva *et al.*, 2019c). Interestingly, only few examples of multipartite genomes were provided for this group of viruses (Nerva *et al.*, 2019c; Lin *et al.*, 2019; Velasco *et al.*, 2019) whereas for most of them only the RdRP was identified. This last evidence is probably due to the fact that sequences encoding for the nucleocapsid (Nc) and the non-structural protein (Ns1) are not conserved with that of plant and animal viruses, reducing the ability of researchers to identify them through bioinformatics approaches.

Finally, among the dsRNA clade there are many families hosting mycoviruses, with a variegated genome organization and for which virus particles have been often characterized (Fig. 1). For example, the *Totiviridae* family hosts many mycoviruses with a unique genome segment, encoding for two proteins: the RdRP and the coat protein (CP) which build the virus particle (Wickner *et al.*, 2012). This family host a number of viruses infecting not only fungi, but also insects, animals and plants. In addition, one of the most interesting discoveries over the last few years concerns the interaction between a *Totivirus* species and an unrelated + ssRNA mycovirus (Zhang *et al.*, 2016). It has been demonstrated that, a mycovirus belonging to the dsRNA clade is able to share both the capsid protein and the RdRP with an unrelated mycovirus which infect the same fungal strain (Zhang *et al.*, 2016). This research demonstrated that also viruses can be parasitized, or at least that can share indispensable molecular machinery to achieve the host infection and spread into the environment. In addition to the monopartite group, there are also mycoviruses with bipartite genomes. The above mentioned *Curvularia thermal tolerance virus* belongs to a still undefined group of viruses which shows two genome segments. In detail, the latter viruses display an RNA 1 encoding for the RdRP and an RNA 2 which encodes for two proteins: the capsid and a protein with a still undefined function (Marquez *et al.*, 2007; Nerva *et al.*, 2016). A second independent group of bipartite viruses is the family *Partitiviridae*. Also for this group of viruses RNA 1 encodes for the RdRP while the RNA 2 encodes only for the capsid protein (Nibert *et al.*, 2014). In addition, some partitiviruses have also a third genome segment which encodes for a protein with an undefined function that is not indispensable for virus replication (Deng *et al.*, 2017; Jiang *et al.*, 2019; Kotta-Loizou and Coutts, 2017a). Finally, another important viral family hosting mycoviruses is the *Chrysoviridae* family (Ghabrial and Castón, 2011). This group of viruses have a quadripartite genome structure, with the RNA1 encoding for the RdRP, the RNA2 encoding for the coat protein while RNA 3 and RNA 4 encode for two protein with unknown functions (Jiang and Ghabrial, 2004).

It is conceivable that in the next years, thanks to the wide distribution of NGS techniques, the number of viral families hosting mycoviruses will increase considerably.

Evolutionary Theories

Up to few years ago, the most accepted theory about mycoviral evolution was the long coevolution theory. The latter proposed that, due to their intracellular mode of transmission and the ability to infect only one or few hosts, over the years mycoviruses coevolved together with their hosts without interaction between them and also with other class of viruses (e.g., plant and animal viruses). Later on, thanks to the NGS techniques and new experimental evidences, this theory has been completely revised.

One of the observations that brought to a new theory is that many viral families (e.g., *Totiviridae*, *Partitiviridae* and *Chrysoviridae*) host species infecting both fungi and plants (Nerva *et al.*, 2017b; Nibert *et al.*, 2014). Among these families, there are species able

Fig. 1 Examples of virus particles from partially purified fungal extracts photographed at Transmission Electron Microscope (TEM). (A) Virus particles from a *Penicillium aurantiogriseum* isolate carrying multiple viral infection. At least three morphologies are visible. Particles of 32–35 nm in diameter, rounded in profile, either penetrated or not by the stain (black arrows). Particles of 39–42 nm in diameter are hexagonal in profile (white arrows). Particles of about 50 nm diameter, rounded in profile (arrowhead). (B) Virus particles from a *Penicillium* spp. carrying a multiple infection. Two distinct type of particles were observed. Particles with 29–32 nm in diameter, rounded in profile and always penetrated by stain (Black arrow). Particles with 40–44 nm in diameter and never penetrated by stain (white arrow). (C) Virus particles from an isolate of *Aspergillus flavus* infected by a partitivirus. (D) Virus particle from an isolate of *Penicillium* spp. infected by a chrysovirus. Bars in each panel represent 50 nm. Credits: Dr. Marta Vallino, IPSP-CNR (Italy).

to infect plants and other able to infect fungi, but no one is able to infect both plants and fungi (Roossinck, 2015). A further link between plant and fungal viruses was proposed for the first time for the *Hypoviridae* family: analysis of protein sequences revealed that they share a common ancestor with the plant-infecting Potyviruses (Koonin *et al.*, 1991). Moreover, many other families showed a mosaic of hosts or peculiar phylogenetic origins which further suggest that exchanges of viruses between plants and fungi can occur (Donaire *et al.*, 2016; Rastgou *et al.*, 2009; Turina *et al.*, 2017; Plyusnin *et al.*, 2012; Attoui *et al.*, 2012). In consequence to these works, to date, the most supported theory suggest that, (1) thanks to the *quasispecies* nature of viruses (Domingo *et al.*, 2012; Roossinck, 1997) and to (2) the close physical relationship with other organisms (e.g., fungal-plant interface), viruses can easily move from the original host to new distant and taxonomically unrelated hosts. This latter hypothesis was demonstrated for both plant and fungal viruses, which are able to replicate in fungi (Janda and Ahlquist, 1993; Panavas and Nagy, 2003; Mascia *et al.*, 2019), and for mycoviruses which are able to replicate in plants cells (Nerva *et al.*, 2017b). In addition, to further support this hypothesis a clear example of viral cross-species transmission between different taxa was proposed for viruses of several plants and arthropods (Shi *et al.*, 2016).

Another interesting case of mycoviral evolution is linked to the mitoviruses group. Intriguingly, species belonging to *Mitovirus* genus are closely related to the *Leviviridae* family, the only well-defined group of +ssRNA bacterial phages (Turina *et al.*, 2017; Dolja and Koonin, 2018). Considering the theory of mitochondria derived from an ancestral alphaproteobacterial endosymbiont (Raven, 1970), this evidence suggests that mitoviruses are derived from a mitochondrial phage by losing the capsid protein (Koonin *et al.*, 2015), which is unnecessary due to the lack of an extracellular stage (Koonin and Dolja, 2014). The main objection to this theory was that, up to 2018, no evidence of mitovirus sequences was found out from fungi. Then, using bioinformatics

approaches (Nibert *et al.*, 2018) followed by biological characterization of a true replicating virus, mitoviruses were reported also in plants (Nerva *et al.*, 2019e).

All these reports highlighted the importance of viral evolution studies: since fungi are ubiquitous in the environment and often infected by viruses they can play a very important role in defining the virosphere of a specific ecological niche.

Impact on Fungal Behavior

Although mycoviruses are common among fungi, they often remain latent without inducing obvious symptoms in their host, at least in axenic condition (Pearson *et al.*, 2009). In some case, however, they can cause dramatic alteration in their inhabited fungi, including irregular growth, changes in pigmentation, cytological alterations of cellular organelles, changes in enzymatic activities and altered sexual and asexual reproduction (Ghabrial *et al.*, 2015; Jiang *et al.*, 2013; Nuss, 2005; Newhouse *et al.*, 1983; Rigling and Van Alfen, 1993). In addition, the biological and ecological role(s) that mycoviruses play over the multitrophic interactions is largely unknown and further complicated by frequent multiple viral infections (Khalifa and Pearson, 2013; Picarelli *et al.*, 2019; Nerva *et al.*, 2019c).

One of the most important and earliest research on mycoviruses concerned the interaction between the hypovirus *Cryphonectria hypovirus 1* (CHV1) and the chestnut blight fungus *Cryphonectria parasitica*. Virus-infected isolates displayed lower production of spores, an altered pigmentation, a reduced growth in axenic conditions and a reduced virulence in the host plant (*Castanea* spp.) which led to the definition of hypovirulence (Sotirovski *et al.*, 2006; Rigling *et al.*, 1989; Hillman *et al.*, 1990; Hillman and Suzuki, 2004; Turina *et al.*, 2006). As cited before, the latter was only the first report, followed by many other hypovirulence-associated mycoviruses. To date, viruses able to confer the hypovirulent trait have dsRNA, + ssRNA, and circular ssDNA genomes and include representatives of the *Totiviridae*, *Naviridae*, *Chrysoviridae*, *Reoviridae* and *Genomoviridae* which infect both Ascomycota and Basidiomycota fungi (Liu *et al.*, 2015b; Khalifa and Pearson, 2013; Hu *et al.*, 2014; Yu *et al.*, 2015; Xie *et al.*, 2016; Du *et al.*, 2014).

In contrast to hypovirulence, the other interesting phenomenon associated to a mycoviral infections is the hypervirulence, the opposite trait. This last feature is less known than the previous one and it was described only in few reports. So far, the first reported case was with the identification of dsRNAs molecules associated to an hypervirulent isolates of *Nectria radicola* (Ahn and Lee, 2001) which attack the ginseng root. Some years later, the simultaneous description of two partitiviruses inducing the hypervirulence phenotype on *Trichoderma harzianum* and *Talaromyces marneffei* have been noticed (Lau *et al.*, 2018; Chun *et al.*, 2018). The latter example is of particular interest for human health since *T. marneffei* is a pathogen able to cause systemic mycosis which can lead to death of immunocompromised patients (Lau *et al.*, 2018).

The alteration of the fungal behavior above described is probably associated to an altered fungal metabolism. Mycoviruses are obligate intracellular parasites which reprogram the entire host metabolism in order to replicate within host cells avoiding antiviral responses (Collum *et al.*, 2016; Hurwitz *et al.*, 2013). The most studied fungal model system to deepen the metabolic changes in consequence to mycoviral infection is the largely studied *C. parasitica*. In fact, it was demonstrated that viral infection induces an extensive modulation of metabolites belonging to classes of amino acids, carbohydrates, lipids, nucleotides and polyamines (Dawe *et al.*, 2009). In addition, it was also demonstrated that infection of *C. parasitica* with a virus from an unrelated fungus led to an enhanced resilience to osmotic stress (Nerva *et al.*, 2017a), suggesting the possibility of an overlapping between the fungal responses to biotic and abiotic stresses. Finally, it was also demonstrated that secondary metabolites can be modulated by the mycoviral infection as reported for the AK-toxin of *Alternaria alternata* or the ochratoxin A (OTA) in *Aspergillus ochraceus* (Nerva *et al.*, 2019a; Okada *et al.*, 2018).

Over the last decades, the intriguing concept of “good viruses” (Roossinck, 2011; Virgin, 2014) has been proposed to highlight that virus-host relationship are often mutualistic. This concept seems to well-fit with most of the case observed for mycovirus-fungus interaction, which often induce an enhanced fitness through the expression of genes and metabolites that partially overlap those activated during abiotic stresses (Bostock, 2005). Also in this case many researches are needed to uncover the potentiality of mycoviruses and to better elucidate their effects at cellular level.

Mycoviruses as Triggers and Target of RNA Silencing Machinery

RNA silencing is an evolutionarily conserved pathway which was first described in *Caenorhabditis elegans* as a phenomenon called RNA interference (RNAi) (Fire *et al.*, 1998). A similar pathway was also described in plants (Napoli *et al.*, 1990) and fungi (Romano and Macino, 1992). This silencing system is activated in response to invasive nucleic acids, and in specific against dsRNAs. It induces a specific defense response against the invasive agent (e.g., viruses, retrotransposon, transgene, etc.) by cutting the dsRNAs into small RNAs (Ding and Voinnet, 2007; Chapman and Carrington, 2007). The latter lead to the degradation of target RNAs and for this reason are also known as small interfering RNA (siRNA). In plants and fungi, replicating RNA viruses initiate the RNA silencing response by forming replicative double-stranded RNAs (dsRNAs) which are recognized by specific ribonucleases, the dicer proteins (dcl) which lead to the production of 21– to 24–nucleotides virus-derived small RNAs (vsiRNAs) (Ding and Voinnet, 2007).

Although vsiRNAs have been extensively profiled in many plant and animal species, little is known about composition and role (s) of such RNAs in fungal cells while a mycovirus infection is ongoing. The antiviral role of RNA silencing in fungi was first described in *Cryphonectria parasitica* infected by the mycovirus CHV1 (Nuss, 2011) and then many other researches demonstrated the activity of an RNAi pathway in fungi (Himeno *et al.*, 2010; Wang *et al.*, 2016; Vainio *et al.*, 2015). Although fungi confirmed to

have an active antiviral defense, some species displayed peculiar characteristics. For example, length of vsiRNAs is not conserved among fungi: some species display a production of 21 nucleotides long vsiRNAs, consistent with that of plants, whereas some others display a completely different size distributions which range from 21 up to 30 nucleotides (Himeno *et al.*, 2010; Nakayashiki and Nguyen, 2008; Mochama *et al.*, 2018; Nerva *et al.*, 2016). In addition, some fungal species, such as *Saccharomyces cerevisiae* and *Ustilago maydis*, have completely lost the silencing machinery (Nakayashiki and Nguyen, 2008), suggesting the existence of different strategies to counteract viral infections.

Biotechnological Applications and Future Perspectives

To date, there are only two existing example of mycovirus biotechnologically exploited. The first is represented by the case of CHV1. The plant pathogen *Cryphonectria parasitica*, imported from Asia in the United State of America at the end of nineteen centuries, is responsible for the near-disappearance of the American chestnut, *Castanea dentata*, from its natural environment (Anagnostakis, 1987; Nuss, 2005). The fungus was then imported from USA to Europe, described for the first time in Italy on sweet chestnut (*Castanea sativa*) in 1938 (Biraghi, 1946) and then spread to the most of the European countries. Thanks to many efforts, during 1950s it was discovered the biocontrol potential of CHV1 (Grente, 1965; Elliston, 1985) which was then routinely used for the disease control (Elliston, 1985; Choi and Nuss, 1992; Nuss, 1992). Thanks to the exploitation of CHV1, in Europe, chestnut blight is no more threatening the survival of *Castanea* spp. demonstrating the potential of mycoviruses in modulating virulence of plant pathogens.

The second case of a biotechnologically exploited mycovirus is the so called “killer yeast” system for toxin production. Many yeast isolates secrete killer toxins that inhibit growth of other species and/or strains (Marquina *et al.*, 2002). These toxins have no activity against microorganisms other than yeasts, and the killer strains are insensitive to their own toxins (Liu *et al.*, 2015a). Studies on the nature of the killing phenomenon showed the involvement of double-stranded RNAs elements associated with virus-like particles (VLPs) which were then identified as mycoviruses (Bostian *et al.*, 1980; Herring and Bevan, 1977). From that moment, killer isolates have been used to control contaminating yeasts in food commodities and to control pathogenic fungi in plants (Schmitt and Breinig, 2002). In details, killer yeasts have been used to control contamination in the winemaking and brewing processes (Schmitt and Breinig, 2002) as well as to develop novel antifungal drugs for the treatment of human and animal mycoses (Magliani *et al.*, 2008).

Despite CHV1 remains the only example of large scale application, a number of other reports suggest the possibility of exploiting mycoviruses as sustainable tool in plant defense strategies. For example, the potentiality of *Sclerotinia sclerotiorum hypovirulence-associated DNA virus 1* (SsHADV-1) as natural fungicide was proved in *Arabidopsis thaliana* and *Brassica napus*. SsHADV-1 is a circular ssDNA virus which displayed the ability to be transmitted extracellularly when applied to the fungus both in vitro and in vivo (Yu *et al.*, 2013). Interestingly its virus particle displayed a good stability when applied on leaves of plants, remaining detectable up to 15 days after application. Moreover, the crude preparation of virus particles applied on plants inhibited the expansion of fungal pathogen and cured the lesion (Yu *et al.*, 2013). Finally, the same virus can infect a mycophagous insect and use it as transmission vector (Liu *et al.*, 2016). All together these results demonstrated once again the potentiality of mycoviruses as biological control agents for a sustainable plant protection and are pushing the researchers to identify new viral species.

In addition to the hypovirulence traits for plant protection purposes there are other scientific works that suggested the biotechnological potential of mycoviruses. For example, their use in enhancing the host virulence can be exploited to improve action of fungi as biological control agents against other pathogens. This was the case of viruses associated to *Trichoderma* spp., a widely used mycoparasitic fungus, which displayed an enhanced antifungal activity when infected by a mycovirus (Chun *et al.*, 2018). On the contrary, it was demonstrated that infection by a specific mycovirus induce hypovirulence in *Beauveria bassiana* (Kotta-Loizou and Coutts, 2017b), an entomopathogenic fungus with a wide host range and used as a biocontrol agent against arthropod pests.

Finally, the use of mycoviruses as biological control agents can be a suitable alternative also for treatment of systemic mycoses in human patients. In the last few years a growing number of human pathogens displayed resistance against antifungal compounds (McCarthy *et al.*, 2017), highlighting the urgent need for new therapeutic strategies. In this line, one hypothetical therapeutic strategy might involve the use of mycoviruses (van de Sande *et al.*, 2010), which selectively infect one or few fungal species preserving the human holobiome. All together these findings displayed the importance of looking at the virological state of fungi, especially when used in biotechnological purposes. In addition, considering the mycological collections, knowing the viral state of a fungal isolate is very important since isogenic virus-free and virus-infected isolates can display different characteristics and behavior. In conclusion, the potential use of mycoviruses may have significant ecological and economic implications and for these reasons deserve more attention over the next future.

Introduction: The Extensive Diversity of Repetitive DNA in Fungal Genomes

Repetitive elements comprise both DNA sequences that are present in multicopies in genomes and ubiquitous in eukaryotic genomes (Biscotti *et al.*, 2015). Major contributors of these repetitive sequences are the tandem repeats including microsatellites and transposable elements (TEs). In humans and other mammals, TEs represent up to 50% of the total DNA (Zamudio and Bourc'His, 2010) while, in plants it can reach more than 80% (Schnable *et al.*, 2009). In fungal genomes the range of repeat content is extremely variable. For instance, TEs represent approximatively 3% of the yeast *Saccharomyces cerevisiae* genome (Kim *et al.*, 1998), up to 58% in the black truffle *Tuber melanosporum* (Martin *et al.*, 2010) and covers more than 90% in the soybean pathogen *Phakopsora pachyrhizi* (Sebastien Duplessis, personal communication). For decades, TEs were described as “selfish” DNA elements of host genomes after first being described in maize by McClintock (1984) and Biémont (2010). TEs can replicate autonomously and thereby can be regarded as “self-existing”, independent of the host genome, and were eventually considered as “junk” DNA. However, growing evidence from genomics, population genomics and functional analysis studies have demonstrated that TEs can also have a major role for genome evolution (Dubin *et al.*, 2018). In maize for example, TEs associate in maize development such as flowering time (Castelletti *et al.*, 2014), specific TEs exhibit signatures of selection (Studer *et al.*, 2011) and drought tolerance adaptation (Mao *et al.*, 2015). TEs can have considerable consequences on host genome evolution, architecture and plasticity (Castanera *et al.*, 2016). TEs evolutionary success relies not only in their ability to replicate faster than the host genome, but also because TEs can be transmitted both vertically and horizontally (Gilbert and Feschotte, 2018).

A systematic classification system was established to categorize the extensive diversity of TEs based on their function and origin (Wicker *et al.*, 2007). To help TE identification and annotation, a hierarchical classification has been defined, based on transposition mechanisms that distinguish two classes of TEs: retrotransposons and DNA transposons (Fig. 1) (see (Wicker *et al.*, 2007) for detailed classification of TEs). The two classes of TEs divide into subclasses, orders and superfamilies depending on respectively, proteins or non-coding domain structures, target site duplication length and DNA sequence conservation (Fig. 1) (Wicker *et al.*, 2007). TEs further divide into families that are mostly species-specific or shared only by closely related sister species. Retrotransposons (or Class I) require a RNA intermediate reverse-transcribed into cDNA that integrates in a new position in the genome. The class I transposition mechanism is commonly referred to as a “copy-and-paste” mechanism (Boeke *et al.*, 1985). Each transposition event of a retrotransposon produces an additional copy which explains that retrotransposons often contribute to the main fraction of repeat content in many fungal genomes (Fig. 1(A)) (Martin *et al.*, 2008, 2010; Duplessis *et al.*, 2011; Grandaubert *et al.*, 2014; Grandaubert *et al.*, 2015). Retrotransposons comprise five orders namely: Long terminal repeats (LTR) elements, *Dictyostelium* intermediate repeat sequence (DIRS), Penelope-like elements (PLEs), Long Interspersed Elements (LINEs) and non-autonomous Short Interspersed Elements (SINEs). DNA TEs (Class II) consist of two subclasses. Elements of Subclass 1 use a “cut-and-paste” transposition mechanism, where both strands of the DNA are excised. Elements of Subclass 2 replicate by single strand excision and a rolling-circle mechanism (Helitron) or an unknown mechanism (Maverick or Pollinton) (Greenblatt and Brink, 1963; Rubin *et al.*, 1982; Kapitonov and Jurka, 2007). DNA transposons are divided in five orders: Terminal inverted repeat (TIR), Crypton, Helitron and Maverick (Wicker *et al.*, 2007). In addition, class II contains the sub-family of Miniature inverted-repeat transposable element (MITEs) that are the non-autonomous counterpart of TIR (Fig. 1(A)). Non-autonomous TEs including SINEs, TRIM, LARD, MITEs and some Helitrons use the replication machinery of other TEs or genes to transpose. Both MITEs and SINEs are small elements of less than 1000 bp and rely respectively on TIR transposases and LINEs retro-transcriptase to transpose (González and Petrov, 2009; Kramerov and Vassetzky, 2011). The autonomous or non-autonomous status of the different TEs families that colonize fungal genomes have dramatically different impacts on the host genome architecture, notably by inducing structural variation within populations (Badet *et al.*, 2020). In addition, TEs uncontrolled expansions have been demonstrated to induce genome instability even leading to decrease of host fitness (Pasyukova *et al.*, 2004; Zamudio and Bourc'His, 2010).

New TE insertions can have different consequences on host fitness depending on their insertion sites (Fig. 1(B)). Overall, the fitness cost of TE insertions has been estimated as deleterious (Horváth *et al.*, 2017). TE insertions into coding or regulatory regions can lead to exonization, truncation, alternative splicing or modification of gene expression (Fig. 1(B)) (Bourque *et al.*, 2018).

A	Class	Order	Structure
Class I Retrotransposons	LTR		
	LINE		
	SINE		
	DIRS		
	Penelope		
Class II DNA transposons	TIR		
	Crypton		
	Helitron		
	Maverick		
	MITE		

However, gene and transcription modifications are not the only consequences of TEs activity in fungal genomes. At a genome organization level, TEs are involved in telomere maintenance, chromosomal rearrangements, genome compartmentalization and genome size expansions (Möller and Stukenbrock, 2017). However as TEs accumulate independently in their host genome, differences in TEs content have been observed between lineages (Oggenfuss *et al.*, 2020). TEs content variation between two lineages was documented to have prevented gene flow between fungal populations (Giraud *et al.*, 2008). Chromosomal rearrangements can be associated with suppression of recombination and thus represent a barrier to gene flow (Serrato-Capuchina and Matute, 2018). Hence, TEs represent a source of speciation agents (Serrato-Capuchina and Matute, 2018). Sexual reproduction in fungi is based on mating systems whereby different mating types control sexual reproduction outcome (Nielsen and Heitman, 2007). Two mating system strategies can be found in closely related species: homothallism (i.e. self-compatibility) and heterothallism (i.e., self-incompatibility) (Wilson *et al.*, 2015). In several fungal clades, homothallic/heterothallic transitions among closely related species associate with TE activity within or nearby mating-type loci (Rusche and Rine, 2010; Gioti *et al.*, 2012). Finally, it has been hypothesized that the variation in TE content of fungal genomes could be linked to their life-style (Muszewska *et al.*, 2019). Comparative genomics studies demonstrated that TE content and composition depend on the history of TE invasions and expansions in the host species rather than phylogenetic proximity (Hess *et al.*, 2014; Amselem *et al.*, 2015b). Interestingly, by comparing TE content across the fungal kingdom it appears that symbiotic ectomycorrhizal fungi or obligate biotrophic pathogens exhibit a high TE coverage compared to saprophytes (Fig. 2). For instance, the tree mutualist *Coenococcum geophilum* (Peter *et al.*, 2016; de Freitas Pereira *et al.*, 2018) and the powdery mildew pathogen *Blumeria graminis* (Frantzeskakis *et al.*, 2018) exhibit 75% and 90% of TE content in their genomes, respectively. The various impacts on host genome evolution reflect the long-term coevolution between TEs and host genomes in fungi.

TEs are known to be deleterious to the host, and fungal species have evolved a variety of defense mechanisms to counterbalance negative impacts on fitness due to TEs invasions and expansions. These mechanisms are largely conserved across animal, plant and fungal genomes and mostly involve epigenetic silencing through DNA methylation, small RNA silencing and histone modification mediated silencing (Feng *et al.*, 2010; Gladyshev, 2017; Möller and Stukenbrock, 2017). A particular and highly efficient defense mechanism in fungi is called Repeat-Induced Point (RIP) mutation (for detailed review see (Gladyshev, 2017)). The RIP mechanism was first described when high level of cytosine-to-thymine mutations and cytosine DNA methylation were observed in duplicated genes of the model system *Neurospora crassa* (Selker and Stevens, 1985). RIP mechanism is currently understood as a two-step process involving cytosine methylation followed by deamination (Gladyshev and Kleckner, 2017). RIP specifically targets duplicated sequences independently of their expression and can spill over to neighboring sequences (Irelan *et al.*, 1994). TE insertions can also be counter-selected in fungal populations at variable strengths depending on their negative effect and the effective population size. Advantageous insertions can potentially be favored by selection and rise in frequency. The genomes of some fungal species are organized in specific TE rich compartments, whereby TEs are associated with rapidly evolving genes and signatures of recent adaptation, often referred as “two-speed” genomes (Dean *et al.*, 2005; Rouxel *et al.*, 2011; de Jonge *et al.*, 2013; Grandaubert *et al.*, 2014; Dong *et al.*, 2015). In addition, silenced TEs can be de-repressed under various stress and developmental stages. Thereby in specific conditions, TEs mobilization may help rapid adaptation to diverse stress conditions (Fouché *et al.*, 2020). Understanding how genomes regulate TEs activity is crucial to understand the diversity of TEs dynamics and impacts across fungi.

Major progress has recently been made to comprehend TEs dynamics in fungal genomes. However, the evolutionary interplay between a host genome and TE invaders is yet to be fully understood. Our current understanding of TE impact on fungal genome evolution is mainly based on comparative genomic studies and few functional analyses in model systems. Most studies agree that TE activity has overall a negative impact on host fitness, notably because TE insertions can induce phenotypic changes either directly (i.e., through gene disruption or expression modification) or indirectly (i.e., by triggering epigenetic changes). Thereby, TE activity can also represent a key mechanism for rapid adaptation. Understanding the impact of TEs on the adaptation of the host requires to deeply study TE dynamics in fungal populations including how effectively genomic defenses prevent proliferation. This chapter provides an overview of how various host genome defense mechanisms regulate TE activity in fungi. Furthermore, we provide insights into how the host population demography impacts TE dynamics. Finally, we summarize the compartment and locus-specific effect of TEs on fungal genome architecture and plasticity.

Fig. 1 Transposable element (TE) structure and effects on genes. (A) class and order of transposable elements based on classification in Wicker *et al.* Class I groups retrotransposons using an RNA transposition intermediate. Class I comprises five orders depending on reverse transcriptase phylogeny and TE structure: LTR, long terminal repeats; LINE, long interspersed nuclear element; SINE, short interspersed nuclear element; DIRS, *Dictyostelium* intermediate repeat sequence; Penelope, *Penelope*-like elements. Class II groups DNA TEs and lack RNA intermediate. Class II comprise five orders depending on the number of DNA strands cut during transposition: TIR, terminal inverted repeats; Crypton; Helitron; Maverick; MITE, miniature inverted-repeat transposable element. Pol, DNA polymerase; gag, capsid protein; ORF, open reading frame of unknown function; EN, endonuclease; RT, reverse transcriptase; TR, tyrosine recombinase; RPA, replication protein A; INT, integrase. (B) Effect of TE insertion on gene transcription and regulation. *MITEs are not considered as an order but as the non-autonomous counterpart of TIR. (i) TE insertion upstream of gene-coding regions can lead to promoter disruption either directly or indirectly through epigenetic silencing; (ii) exonic and (iii) intronic TE insertions can lead to truncated transcripts, alternative splicing or exonization; (iv) downstream insertions potentially add small RNA binding or polyadenylation sites and (v) TE insertion can integrate into coding regions leading to the generation of chimeric genes also known as TE domestication. TE, transposable element. Reproduced from Wicker, T., *et al.*, 2007. A unified classification system for eukaryotic transposable elements. *Nat. Rev. Genet.* 8 (12), 973–982. doi:10.1038/nrg2165.

The Fine-Tuned Regulation of Transposable Elements Proliferation

Coevolution of host genomes and TEs determines the extent and activity of TEs in a genome. In fungi, the majority of TE copies are transcriptionally inactive except under environmental stress conditions (Fouché *et al.*, 2020). Epigenetic silencing is widespread along the genome, affecting both genes and TE expression (Huda *et al.*, 2010; Freitag, 2017; Borgognone *et al.*, 2018). Epigenetic TE silencing mechanisms occur at three different levels: (1) chromatin structure and histone modifications, (2) DNA methylation and (3) small RNA silencing. The following section describes how epigenetic silencing of TEs varies across the fungal tree of life.

Epigenetic Silencing due to Histone Methylation

Chromatin modifications are essential for genome stability notably regarding silencing of TEs in fungal genomes. The high compaction of heterochromatin lead to inaccessibility of transcription machinery (Möller *et al.*, 2019). In fungal genomes, expressed genes often associates within euchromatin while TEs associate with heterochromatin regions (Lewis *et al.*, 2009; Connolly *et al.*, 2013; Chujo and Scott, 2014; Galazka and Freitag, 2014; Schotanus *et al.*, 2015; Feurtey *et al.*, 2020). Different histone modifications specifically mark euchromatic or heterochromatic regions. Euchromatin is marked by H3 lysine 4 di- or trimethylation (H3K4me2/3) while heterochromatin associates with H3K9me2/3 and H3K27me2/3 (Freitag, 2017). Histone modifications are a reversible epigenetic process. In fungi, change in the histone modification marks, notably due to TE insertions, can provide a source for rapid adaptation under stress conditions, pathogenicity and for the regulation of secondary metabolite gene clusters (Chujo and Scott, 2014; Soyer *et al.*, 2014; Krishnan *et al.*, 2018; Fouché *et al.*, 2020).

DNA Methylation

Similarly to animals and plants, DNA methylation can target cytosines of duplicated sequences including TEs in fungal genomes. Although widespread across eukaryotes, impact of the 5-methylcytosine modified (5mC) base on gene expression, TE silencing and genome integrity varies between taxa (Slotkin and Martienssen, 2007; Jones, 2012; Bewick *et al.*, 2019). DNA methylation is specifically mediated by DNA methyltransferases (DNMTs) that can either establish (*de novo* DNMTs) or maintain (*maintenance* DNMTs) DNA methylation (Lyko, 2018). DNMTs are part of a large protein family and are classified in different clades in function of their conserved domains and activities (Bewick *et al.*, 2019) (Fig. 2). In fungi, a recent extensive phylogenetic study of DNMTs across more than 500 fungal species revealed a wide presence/absence variation in DNMTs content between closely related species (Bewick *et al.*, 2019). This study described that fungal DNMTs are part of five superfamilies namely DNMT1, DIM-2, RID, DNMT2 and DNMT5 (Bewick *et al.*, 2019). Bewick *et al.* (2019) also showed that DNMTs duplications and losses shaped DNMT genes evolution in eukaryotes. DNMTs show a remarkable presence/absence variation in closely related species with the highest diversity found in Ascomycota whereby some species exhibit all DNMTs (e.g., *Chalara longipes*; Fig. 2) (Bewick *et al.*, 2019). Basidiomycota species mostly carry DNMT1 and DNMT5 while RID and DIM-2 are absent (Fig. 2). DIM-2 and RID are known to be the key players of RIP mechanism through specific 5mC methylation of duplicated sequences demonstrated in *N. crassa* (Gladyshev and Kleckner, 2014; Mazur and Gladyshev, 2018). DIM-2 and RID can be lost between closely related fungal clades. For instance, Möller and colleagues recently showed an intra-specific presence/absence variation of DNMT proteins in the wheat pathogen *Z. tritici* isolates due to accidental RIP in genes coding DIM-2 (Möller *et al.*, personal communication) (Dhillon *et al.*, 2010). *Z. tritici* isolates sampled at the species center of origin possess active DIM-2 and DNMT5 while *Z. tritici* isolates sampled outside the center of origin possess only DNMT5. Interestingly, the loss of DIM-2 and thereby the reduction of 5mC in *Z. tritici* isolates associates with a reduction in RIP signatures on TEs (Lorrain *et al.*, personal communication). Understanding TE invasion dynamics in fungal genomes requires to evaluate how TEs co-evolved with genome defense mechanisms. Fungal species deploy a variety of mechanisms including the irreversible mutation accumulation of TEs mediated by the RIP mechanism. Mutations induced by RIP in fungi challenges the dating of specific TE family invasions and the identification of ancestral sequences (Grandaubert *et al.*, 2014). The RIP mechanism has been demonstrated to be costly to maintain and can be lost between closely related species (Galagan and Selker, 2004). Interestingly, a modeling approach conducted in the model plant *Arabidopsis thaliana* showed that the retention of methylated TEs could be more efficient to prevent transposition than elimination (Roessler *et al.*, 2018). It would be interesting to investigate if TE regulation converges on similar mechanisms in fungal species with highly repetitive genomes such as in the Pucciniales (Basidiomycetes).

Fig. 2 Repertoires of DNA methyltransferases genes in Ascomycetes and Basidiomycetes. Phylogenetic representation of 5-methylcytosine methyltransferases in 29 fungal genomes including 15 Ascomycetes (*Tuber melanosporum*; *Aspergillus flavus*; *Zymoseptoria tritici*; *Pyrenophora tritici-repentis*; *Pseudocercospora fijiensis*; *Parastagonospora nodorum*; *Leptosphaeria maculans*; *Geonococcum geophilum*; *Chalara longipes*; *Blumeria graminis*; *Verticillium dahlia*; *Neurospora crassa*; *Magnaporthe oryzae*; *Fusarium graminearum*; *Colletotrichum graminicola*) and 14 Basidiomycetes (*Agaricus bisporus*; *Hebeloma cylindrosporum*; *Heterobasidion annosum*; *Laccaria bicolor*; *Paxillus involutus*; *Phanerochaete chrysosporium*; *Piriformospora indica*; *Pisolithus tinctorius*; *Pleurotus ostreatus*; *Microbotryum lychnidis-dioicae*; *Rhodospodium toruloides*; *Melampsora larici-populina*; *Puccinia graminis* f. sp. *tritici*; *Puccinia striiformis* f. sp. *tritici*). Fungal 5-methylcytosine methyltransferases were extracted from (Bewick *et al.*) and comprise DNMT1; DNMT2a; DNMT5; DIM-2; RID. DIM-2 and RID are involved in the Repeat-induced point (RIP) mutation mechanism. DIM-2 and RID were lost by a majority of Basidiomycetes while showing a patchy phylogenetic distribution among ascomycetes. Reproduced from Bewick, A.J., *et al.*, 2019. Diversity of cytosine methylation across the fungal tree of life. Nat. Ecol. Evol. 3 (3), 479–490. doi:10.1038/s41559-019-0810-9. Gladyshev, E., 2017. Repeat-induced point mutation and other genome defense mechanisms in fungi. Microbiol. Spectr. 5 (4). doi:10.1128/microbiolspec.FUNK-0042-2017.

Small RNA Silencing

Another level of TE activity regulation deployed by the host genome uses interfering RNAs (RNAi). In animals, TE epigenetic silencing can be mediated by small-interfering RNAs (siRNA) and piwi-interacting RNAs (piRNAs) (Luo and Lu, 2017). In *Arabidopsis*, small amounts of RNAi were shown to be sufficient to initiate methylation and silencing. Growing evidence suggests that RNAi-mediated TE regulation in fungal genomes is important, however the molecular interplay of RNAi-mediated TE silencing remains largely unknown in most fungal species. RNAi-mediated TE silencing has been described mostly in model organisms such as the fission yeast *Schizosaccharomyces pombe*, the filamentous ascomycete *N. crassa* and the basidiomycete *Cryptococcus neoformans* (Alper et al., 2012; Gladyshev, 2017). In *S. pombe*, RNAi are required for heterochromatin assembly (Alper et al., 2012). RNAi-mediated silencing of TEs was demonstrated in *Cryptococcus neoformans* to be mediated by Spliceosome-Coupled And Nuclear RNAi complex (SCANR) (Dumesic et al., 2013). This mechanism uses the RNAi response to silence pre-mRNAs of retrotransposons in vegetative cells and induces stalling of spliceosomes. Interestingly, TE activity also produces TE-derived small RNAs that are involved in TE silencing in *M. oryzae* (Nunes et al., 2011). Finally, in a recent study of the wheat stem rust fungus *Puccinia graminis* f. sp. *tritici* authors observed a wave of small RNA targeting TEs during late stages of the host plant infection, suggesting epigenetic TE silencing (Sperschneider et al., 2018). Further analyses of TE silencing by small RNAs is a particularly interesting field to understand TE control in genomes that lack the RIP mechanism such as in Basidiomycetes of the order Pucciniales.

Host Population Dynamics Impact Transposable Element Landscapes in Fungi

Investigations of TEs landscapes and dynamics in fungal genomes should not only need to be addressed in regards to their interplay with host genome regulation pathways but also in regards to host genome evolution at the population level. Despite the efforts to unravel molecular mechanisms of TE activity and fungal defense systems, very few studies have investigated TE evolutionary dynamics at the population level in fungal genomics. In the following section, we describe how the demographic history, natural selection and host defense mechanisms modulate TE landscapes in fungal genomes.

The TE Burst and Decay Model

The burst and decay model is used to describe TE evolution (Arkhipova, 2018). Traditionally, the model of TE transposition activity describes the maintenance of an equilibrium between TE insertions (i.e., birth) and TE excisions (i.e., death). In opposition, the burst and decay model assumes activity of TEs only over short periods (i.e., burst), that are counter-balanced by host genome defenses more or less rapidly (i.e., decay).

Overall, number of TE copies increase during short bursts of activity rather than at a constant transposition rate (Vitte and Panaud, 2005; Hua-van et al., 2011; Castanera et al., 2016). Indeed, TEs can sometimes be de-repressed when the host is stressed and thus be expressed and/or mobilized (Horváth et al., 2017; Fouché et al., 2020). The mechanistic basis of de-repression under stress is poorly understood. De-repression may happen due to a trade-off for resource allocation under stress, or de-repression may be an active strategy of the host genome to increase the TE-driven mutation rate. The latter is generally considered as an unlikely scenario, since active TEs are mostly deleterious (Horváth et al., 2017). As above-mentioned, many fungal species have compartmentalized genomes with TE-rich compartments exhibiting relaxed selection (Croll and McDonald, 2012; Raffaele and Kamoun, 2012; Grandaubert et al., 2019; Zhang et al., 2020). De-repressed TEs can cause expansion of the genome size until they undergo decay by being silenced, mutated or truncated by host defenses (Le Rouzic and Capy, 2005).

The estimation of insertion rate and age are the core parameters to model TE population dynamics (Arkhipova, 2018). Recent insertions show an excess of low frequencies in population while ancient insertions are more likely to show inconsistencies in frequency spectra depending on the efficacy of host genome defense mechanisms. (Fig. 3(A)). Over time, most TE copies in a genome can lose function either through mutation accumulation, partial deletions by illegitimate recombination (Devos et al., 2002), or sequence disruption by nested insertions of other TEs (SanMiguel et al., 1996). The age of a TE insertion can be estimated from sequence similarity with other copies in the genome (Kapitonov and Jurka, 1996; Blumenstiel et al., 2014) or the degree of linkage disequilibrium at the insertion site (González et al., 2008). More specific analyses can be performed e.g., for LTRs with the two long terminal repeats flanking the insertion showing divergence over time (SanMiguel et al., 1998). Age estimation can also be done by comparing the coding sequences of the TE (Bowen and McDonald, 2001; Bergman and Bensasson, 2007). Accumulated mutations in TEs can be calibrated with the genome-wide mutation rate to obtain an age estimation (Bowen and McDonald, 2001). In fungal genomes with active RIP, accumulation of mutation can be excessive which can lead to an overestimation of the age that needs to be taken into account for understanding TE dynamics in RIP-proficient fungal species.

New Transposable Element Insertions are Influenced by Selection and Genetic Drift

As a consequence of TE de-repression and TE bursts, new TE insertions can accumulate in the genome. However, the fate of a new TE insertion in the population is based on a combination of selection and genetic drift. Selection acts on TE insertions when there is an impact on host fitness. Insertions into coding or regulatory regions are mostly deleterious or even lethal for the host. Such TE insertions will be rapidly eliminated from populations by purifying selection leading to an excess of low frequency insertions

Fig. 3 Insertion frequency spectra of transposable elements (TEs) depending on their transposition activity and effect on genome architecture. (A) Recent bursts of transposition (orange) should lead to an excess of singletons. Ancient expansions (blue) should lead to inconsistencies in frequency spectra depending on the efficacy of host genome defense mechanisms. (B) Circos plots of non-compartmentalized (*Melampsora larici-populina* – 110 Mb – no accessory chromosomes) versus compartmentalized (*Zymoseptoria tritici* – 40 Mb – up to eight accessory chromosomes) fungal genomes. TEs (orange) and gene (blue) densities are counted along 100 kb windows per chromosome/linkage group. Core and accessory chromosomes/linkage groups are shown in black and gray, respectively.

(Fig. 3(A)). Strong purifying selection has been shown across plants (*Brachypodium distachyon*) and animals (*Drosophila melanogaster*) as well as in the fungal wheat pathogen *Z. tritici* (Cridland *et al.*, 2013; Stritt *et al.*, 2017; Oggenfuss *et al.*, 2020). The impact of TE insertions on regulatory regions or alteration of gene expression profiles has been shown in fungal populations (Chuong *et al.*, 2017; Omrane *et al.*, 2017). Recent insertions can also rearrange chromosomal regions (Badet *et al.*, 2020; Fouché *et al.*, 2020), duplicate genes (Morgante *et al.*, 2005; Yang and Bennetzen, 2009; Devos, 2010), or delete sequences encoding fungal pathogen effectors (i.e., secreted molecules involved in host colonization establishment and maintenance) recognized by the host plant (Hartmann *et al.*, 2017). While most of these effects are deleterious, TE-induced impacts can also be beneficial and lead to local adaptation (van't Hof *et al.*, 2016) or even to extreme examples of co-option whereby TEs are “domesticated” and evolved to a new host function (Feschotte, 2008).

At the population level, changes in the allele frequency of TE insertions can be heavily influenced by genetic drift (Charlesworth and Langley, 1989; Le Rouzic and Capy, 2005). Bottlenecks in the population size, e.g., during the colonization of new habitat, can reduce genetic diversity. As a consequence of genetic drift, allele frequencies in the population are randomly affected. Hence, genetic drift has also consequences on the TE composition in the genome. Genetic drift can lead to the loss of a newly inserted TE or to an increase in frequency in the population. Drift effects are mostly expected in small effective population sizes and for TE insertions that are nearly neutral. When a fungal pathogen colonizes a new territory (e.g., with infected plant material or by spore dispersal), only a subset of all TE insertions of the original population will be present. Genetic drift can also increase the average TE load in a newly established population if the founder genotypes had unusually high TE loads. The application of fungicides in agriculture and other stressors could cause bottlenecks on plant pathogen populations (Lucas *et al.*, 2015). The expansion of *Z. tritici* across the world induced a series of colonization bottlenecks. A population closest to the center of origin was found to have the lowest amount of TEs in the genome and more recently established populations had substantially higher TE contents (Badet *et al.*, 2020; Oggenfuss *et al.*, 2020).

How can Population Dynamics Lead to Differences in TE Content Among Species?

TE bursts and insertion dynamics in populations determine the overall TE load. De-repression, TE bursts and population bottlenecks may occur following major stresses such as host jumps, domestication events or colonization of new environments (Naito *et al.*, 2006; González *et al.*, 2008; Yoshida *et al.*, 2016). Domestication of fungi happened for culinary or medicinal reasons (Payne *et al.*, 2006). In addition, in a broader definition of domestication, crop pathogens were domesticated to the agricultural landscape in parallel to their hosts (Stukenbrock *et al.*, 2011). In *Aspergillus oryzae* and *Z. tritici*, the domestication was associated with an increase in TE content. Over larger time scales, closely related species can evolve distinct TE content in the genome (Lorrain *et al.*, personal communication). Also, genome size expansions resulting from distinct TE accumulations in closely related species were described in the rubber tree pathogen *Pseudocercospora ulei*, among *Fusarium* and *Puccinia* species (Sandra Sayer, personal communication) (Raffaele and Kamoun, 2012; Schwessinger *et al.*, 2018; Zhang *et al.*, 2020). Rebollo *et al.* (2010) hypothesized that TE activity could ultimately favor speciation by creating distinct phenotypes that become locally adapted. Evidence for major TE-mediated adaptations suggests that TEs could have a profound impact on speciation process in fungi as well.

Are Transposable Elements Essential for Rapid Adaptation?

Genome plasticity provides a source of adaptation to new environments for organisms. Host genome plasticity mediated by TEs suggests that the recruitment of TEs could benefit the host by inducing for example gene expression modifications, translocations and even horizontal gene transfer. The following section illustrates how TE-induced host genome plasticity plays a central role in adaptation to ecological niches.

Transposable Element and Host Genome Compartmentalization

TE activity creates rapidly evolving (i.e., rearranging) compartments accompanied by changes in GC content or epigenetic signatures. In fungi, how TEs have shaped host genome architecture is illustrated by TE clusters, compartments and even entire TE-rich chromosomes (Fig. 3(B)) (Duplessis *et al.*, 2011; Bertazzoni *et al.*, 2018; Chen *et al.*, 2018; Frantzeskakis *et al.*, 2018; Stam *et al.*, 2018). In the grass symbiont *Epichloë festucae* TE-rich regions shape the 3D-structure of the host genome (Winter *et al.*, 2018). TE-rich and gene-poor chromosomes can show presence/absence polymorphisms in populations and are referred to as accessory chromosomes (Goodwin *et al.*, 2011; Croll *et al.*, 2013; Bertazzoni *et al.*, 2018). Interestingly, accessory chromosomes are observed in a growing number of fungal species (for review see (Bertazzoni *et al.*, 2018)). In some species such as the pathogen *F. oxysporum* these TE-rich accessory chromosomes also present signatures of rapid evolution (Fokkens *et al.*, 2018). In two-speed genomes, TE-rich compartments represent reservoirs for rapidly evolving genes involved in specific ecological niche adaptations and are often conditionally dispensable (Dong *et al.*, 2015; Faino *et al.*, 2016; Fouché *et al.*, 2018). For instance, lineage-specific regions enriched in TEs drive plasticity and adaptation in *M. oryzae* and in the wilt pathogen *Verticillium dahliae* (Thon *et al.*, 2006; Faino *et al.*, 2016). The potential role that TEs play in genome plasticity represents a source for rapid adaptation by generating phenotypic variation which is particularly important in the context of rapid host plant-fungal pathogen co-evolution.

Transposable Elements are Activated Under Stress

TEs bursts or de-repression in response to stress are observed in various eukaryotes in response to environmental stress conditions or during different life-cycle stages (Voronova *et al.*, 2014; Romero-Soriano and García Guerreiro, 2016; Hummel *et al.*, 2017; Fouché *et al.*, 2020; Pargana *et al.*, 2020). In plants and animals, TE-induced environmental adaptation is well described (Casacuberta and González, 2013), in fungi however little is known about the factors that can activate TEs. In the pathogen species *Ophiostoma ulmi* and in *A. oryzae*, transposition of *OPHIO* and *Crawler* elements are activated during heat shock stress (Bouvet *et al.*, 2008; Ogasawara *et al.*, 2009). During the early stages of fungal pathogens plant colonization, stress-dependent de-repression can lead to TE activity (Chadha and Sharma, 2014; Fouché *et al.*, 2020). In *Z. tritici* for instance, a recent study compared TE activity under stress conditions including nutrient deprivation and during the early stages of wheat infection (Fouché *et al.*, 2020). Specific Gypsy TE families were upregulated during early stages of wheat infection (Fouché *et al.*, 2020). However, the overall decrease of TE expression *in planta* over-time and the different expression profiles observed between isolates suggested a fine-tuned lineage-specific epigenetic regulation of TE activity during wheat infection (Soyer *et al.*, 2019; Fouché *et al.*, 2020). The impact of TE activity in plant-associated fungi during host colonization still remains largely unexplored but should be taken into account to decipher the molecular interplay during plant infection.

Locus-Specific Effects of Transposable Elements Insertions

Numerous studies have demonstrated that TE insertions modify gene transcription (Fig. 1(B)). Locus-specific modifications by TEs may impact phenotypic traits and confer a selective advantage to the host (Table 1). The phenotypic effects of TE insertions are highly diverse depending on insertions as described in Table 1. For instance, the evolution of carbohydrate-active enzymes (CAZymes) of saprophytes such as Ceratocystidaceae species is matched by concurrent TE expansions (Van Der Nest *et al.*, 2015). The ligninolytic fungal species *Pleurotus ostreatus* and *Phanerochaete chrysosporium* also exhibit TE-induced variation in ligninolytic genes expansion and expression (Gaskell *et al.*, 1995; Castanera *et al.*, 2016). Secondary metabolite gene clusters of plant-pathogenic fungi such as the broad necrotrophic pathogen *Sclerotinia sclerotiorum* are tightly associated with the presence of TEs

Table 1 Locus-specific TE mediated or TE-associated adaptation in fungi

Species	Common name	Function/Gene affected	TE	Direct impact	Reference
<i>Blumeria graminis</i> f.sp. <i>hordei</i>	Powdery mildew pathogen	EKA avirulence effector family	LINE retrotransposons domestication	Multigene family expansion	(Amselem <i>et al.</i> , 2015a)
<i>Ceratocystidaceae</i>	Plant pathogens and saprophytes	Glycoside Hydrolase GH32 family	Retrotransposon and Fot5 pogo-like element proximity	Multigene family expansion	(Van Der Nest <i>et al.</i> , 2015)
<i>Cochliobolus heterostrophus</i>	Corn pathogen	Cluster of polyketide synthase encoding genes	Proximity of TEs	Production of T-toxin in race T	(Santana <i>et al.</i> , 2014)
<i>Epichloë festucae</i>	Grass species endophyte	Alkaloids synthesis pathways	MITE insertions	Abolition of alkaloids synthesis	(Fleetwood <i>et al.</i> , 2011)
<i>Fusarium oxysporum</i> f. sp. <i>lycopersici</i>	Tomato pathogen	SIX effectors	MITE insertions flanking genes	Specific association of MITE TE with effector genes	(Schmidt <i>et al.</i> , 2013)
<i>Magnaporthe oryzae</i>	Rice pathogen	Avr-Pita avirulence effector	Retrotransposon insertion upstream of Avr-Pita genes	Virulence gain	(Chuma <i>et al.</i> , 2011)
<i>Phanerochaete chrysosporium</i>	Wood decaying fungi	Lignin peroxidase gene lip1	Insertion of TE Pce1 upstream	Ligninolytic variation between strains	(Gaskell <i>et al.</i> , 1995)
<i>Pleurotus ostreatus</i>	Saprophyte	Ligninolytic and cell-degrading enzymes	Proximity of TEs	Ligninolytic and cell-degrading enzyme genes expansion	(Castanera <i>et al.</i> , 2016)
<i>Pyrenophora tritici-repentis</i> <i>Parastagnospora nodorum</i> <i>Bipolaris sorokiniana</i>	Wheat pathogens	Host specific toxin ToxA	LTR retrotransposon	Horizontal transfer enabling virulence acquisition	(McDonald <i>et al.</i> , 2019)
<i>Ustilago hordei</i>	Barley smut pathogen	Avirulence effector UHOR_10022	TE insertion in promoter region	Expression modification of UhAVR1p	(Ali <i>et al.</i> , 2014)
<i>Verticillium dahliae</i>	Vascular wilt pathogen	Avirulence effector Ave1	Repeat-rich region highly RIP	Horizontal transfer from host plant	(De Jonge <i>et al.</i> , 2012)
<i>Venturia inaequalis</i>	Apple tree pathogen	CYP51A1 fungicide resistance gene	TE insertion in promoter region	Overexpression of CYP51A1 gene leading to fungicide resistance polymorphisms	(Villani <i>et al.</i> , 2016)
<i>Zymoseptoria tritici</i>	Wheat pathogen	Multidrug efflux resistance gene MFS1	LTR retrotransposon insertion upstream	Overexpression of MFS1 and detoxification higher efficacy	(Omrane <i>et al.</i> , 2017)
<i>Zymoseptoria tritici</i>	Wheat pathogen	Transcription factor Zmr1 gene	LTR retrotransposon insertion upstream	Melanin accumulation variation	(Krishnan <i>et al.</i> , 2018)

close by (Graham-Taylor *et al.*, 2020). For plant-associated fungi, there is growing evidence that effector gene diversification is associated either directly or indirectly with TE activity (Fouché *et al.*, 2018). Indeed, several studies reported close physical associations of effector genes and TEs (Lorrain *et al.*, personal communication)(Rouxel *et al.*, 2011; Grandaubert *et al.*, 2014; Soyer *et al.*, 2014; Dong *et al.*, 2015; Fokkens *et al.*, 2018). Horizontal gene transfers are also mediated by TEs as demonstrated for the acquisition of the toxin-coding gene ToxA in the three wheat pathogens *Pyrenophora tritici-repentis*, *Parastagnospora nodorum* and *Bipolaris sorokiniana* (McDonald *et al.*, 2019). Some effectors directly derived from domesticated TEs such as the EKA avirulence effector family of *B. graminis* f.sp. *hordei* that originated from LINE retrotransposons (Amselem *et al.*, 2015a). TEs are key agents in fungal genome evolution and can generate raw material for rapid adaptation in pathogens involved in evolutionary arm's races with their host (Möller and Stukenbrock, 2017). However, we still lack direct evidence of TE recruitment and domestication by the host genome for specific adaptations.

Perspectives

Coevolution between TEs and the host genome have shaped fungal genome evolution. Decades of research aimed at unraveling the complex interplay between TE activity and defense mechanisms of the hosting fungal genome, including the fungal-specific RIP mutation mechanism. Yet, beyond few model system species such as *N. crassa*, the impact and coevolution of TEs and fungal genomes remain largely unexplored. Comparative genomics studies have described the extreme variability of TE content in fungal genomes (Raffaele and Kamoun, 2012; Amselem *et al.*, 2015b; Muszewska *et al.*, 2019). Nevertheless, the annotation of TEs for population-level analyses of polymorphisms requires high quality genome assemblies which remain challenging for numerous fungal species (e.g., Pucciniales) (Aime *et al.*, 2017). In fungi, studies of TE dynamics at the population level are particularly scarce. Oggenfuss *et al.* investigated TEs insertion dynamics in population of the wheat pathogen *Z. tritici* (Oggenfuss *et al.*, 2020). This study highlights that the detection of TE insertions in large dataset of short reads sequencing remains challenging but is indispensable to unravel TE-driven adaptation.

Experimental evidence of specific TE de-repression under stress conditions is very limited in fungi. Several approaches are possible to analyze TE activity under stress. First, transcriptional profiles of transposable elements in various conditions can be used as a proxy for transposition activation (Fouché *et al.*, 2020). Recent method development for TE-associated RNA-seq data analysis has allowed differential expression analysis of TEs (Jin and Hammell, 2018). Second, sequencing genomes resulting from experimental evolution represents a particularly useful approach to study TE activity. Various stressors such as temperature variation can be applied to different isolates from natural populations. Evolved populations can then be sequenced to assess TE structural variants by comparison to the ancestral genome. Further, TE-driven phenotypic variation among the evolved strains could be identified. Such experimental evolution approaches can also be extended to study the potential fitness costs of transposition regulation mechanisms. Mutants lacking genes involved in TE-regulation mechanisms such as RIP or TE-targeted histone modifications can be used to assess (1) efficacy of the different host defense mechanisms as done in (Möller *et al.*, personal communication) and (2) the fitness cost of highly efficient host defense mechanisms (Galagan and Selker, 2004). Future research should address the impact of TE activity in rapid adaptation of fungi, which is particularly relevant in the context of evolutionary arm races established between fungal pathogen species with their host plants.

An important goal of evolutionary biology is to understand how genotypes and phenotypes are linked. In the post-genomics era, studies have focused on variation at the single nucleotide polymorphism (SNPs) level to explain phenotypic variation. However, SNPs alone can only explain a fraction of the phenotypic variations. Structural variants and transposable element have proven to significantly contribute to phenotypic variation in fungi (de Jonge *et al.*, 2013; Oggenfuss *et al.*, 2020). Both genomics and functional analyses of TE-driven phenotypic effects underpin the importance of TE dynamics in generating phenotypic variability and rapid adaptation to new environments, response to stress conditions or artificial selection pressure (e.g., fungicides; Table 1). Thereby, high-throughput methods are needed to investigate the biological impact of TE insertions at a larger scale. (Akakpo *et al.*, 2020) proposed to use a TE genome-wide association (TE-GWAS) approach to detect TE-associated genetic factors associated with variation in life-history traits. For this, TE-GWAS methods and validation criteria need to be adapted to the low allele frequency of TE insertions. In rice, such an approach revealed that specific low-frequency LTR-retrotransposon insertions are associated with grain width variation (Akakpo *et al.*, 2020). TE-GWAS approaches could be particularly relevant for the high-throughput identification of TE-driven phenotypes in fungi.

Aspergilli, More Than Just Fungi: Shaping the Last Decades of Model Systems

Francesca Degola, University of Parma, Parma, Italy

Introduction

According to the Nobel Prize winning physiologist August Krogh's famous admonition, "A convenient organism exists for every biological problem"; however, since we are warned that we are unlikely to ever know everything about every organism, we should agree on some convenient organism(s) to study in depth. This promoted, over centuries of research, the construction of a body of knowledge in that 'model system' that allows us to design appropriate studies of non-model systems to address important questions about their biology. The *raison d'être* of model organisms is generally thought for the study of a specific area of investigation: biological systems that are simple to employ and control obviously facilitate the experimental work, being accessible and, therefore, "convenient". That's why, traditionally, only a few organisms have been widely used with this ambition: a simplified, manageable system that could be used to study a larger theme of biology, revealing not so much a feature of the system itself. The decision to focus on a particular species (or strain, or variant) for biological research is commonly guided by features focused on the interrelation of various criteria, that in 2019 have been efficiently investigated and clustered in the paper "How to choose your research organism" (Dietrich *et al.*, 2020): this process of selection involves a high degree of variability in terms of how such criteria are combined in every instance of system choice, which implications to take into consideration embrace a range of factors including those that are more material, such as access and tractability (in terms of ease of supply and ethical considerations, standardization and responsiveness efficacy), socio-political concerns (such as various economies in terms of financial and institutional support), available resourcing (including epistemic resources such as previous theories), and promise for the future (as novelty and translational potential).

Nonetheless, the modern world poses modern questions, for which the modern science needs modern, advanced tools, encouraging researchers to extend the set of model organisms to include less-studied and more unusual systems: it's easy to argue that appeals to "convenience" are not sufficient to capture reasoning about organism choice. The transition from a model to non-model organism might not be so immediate, for researchers who intend to face the challenge: the ease in using model systems over years led to the development of specific tools and resources for these organisms (techniques and methods, databases and strain collections, molecular toolkits), that in turn made them even more convenient to be used, discouraging others to work on everything else. It was suggested that the gap in methodology and resources between the selected model organisms and other systems resulted in a linguistic shift in how the term "model organism" was understood, from its original sense to "an organism for which a wealth of tools and resources exist" (Russell *et al.*, 2017). In any case, arriving at a certain point it was necessary to admit that, even if undoubtedly suitable for studying various and fundamental aspects of biology, the major model organisms weren't automatically the best systems for all possible questions of general importance. Exploration of organisms (in some cases, different species) as potential new model systems, to ask central questions about biology that have still remained unanswered, is crucial for the progress in knowledge.

The short life cycle, the small size and the easy handling of some microorganisms make them inexpensive subjects for a wide range of studies; additionally, the opportunity of genetic manipulations offers scientists ample prospects to test their theories, unraveling molecular and metabolic mechanisms. Despite indubitable advantages, the downside of using a model is that it is nearly impossible to predict whether this particular system could be representative of another organism; thus, one major difficulty in choosing the adequate model for a specific biological question is the extrapolation of valid results for the real target organism. Being increasingly supported by scientific evidence, it has been argued that while some mechanisms are unique, others similarly operate across different species. This implies that since the basic blocks of life are common to the most of known species, common processes might involve same pathways, that in turn might share same cellular/molecular knots.

Recently spotlighted by Sheldrake's (2020) book "Entangled Life", that explores its potentialities in changing our understanding of life mechanisms the Kingdom Fungi represents an unparalleled source of model organisms for all eukaryotes: although microbial and unicellular systems, and therefore rather easy to manipulate and modify genetically, fungi are eukaryotic cells, sharing a high degree of similarity with animal cells; additionally, the relevant databases are extended and contain the most complete genetic information to date. Of all its divisions, ascomycetes have had the biggest impact on biology, and, in particular, the genus *Aspergillus*, that includes more than 350 known species of filamentous fungi displaying great differences in habitat, pathogenicity, and metabolic properties. For all the *Aspergillus* species, shared data resources have grown exponentially, now including an increasing amount of contents at fungiDB (Stajich *et al.*, 2012); additionally, resource collections like the American Type Culture Collection (ATCC), the Centraalbureau voor Schimmelcultures (CBS) and the USDA NRRL collection, provide open access to well-characterized research materials. Over 1600 projects using *Aspergillus* (containing transcriptome and genome sequences of diverse species, as well as multiple projects with the reference genome strain FGSC A4) are found in the NCBI Short Read Archive (Pontecorvo *et al.*, 1953), while, due to their industrial role, there is a significant amount of data regarding applied use of these organisms: over 11,500 patents include "Aspergillus", with over 1300 solely in 2013.

Various and detailed are the reasons that made *Aspergillus* spp. an ideal model system for studying the mechanisms controlling development and cell differentiation in multicellular eukaryotes, being also well suited for analyzing biochemical events that characterize the cell cycle and metabolism: after all, the word "fungus" shares the root with the Latin verb "*fungor*" (-, *fungēris*, *functus*

sum, - , *fungi*), which meaning, “to exercise an office or fulfill a function on behalf of someone”, perfectly fits with the use that we are here to discuss. Therefore, we’ll try to shape a comprehensive and likely exhaustive survey about the progress of this success story.

What *Aspergillus* Taught us About Eukaryotic Genome Regulation and Maintenance

Probably the most critical process for the genome maintenance is the DNA repair: interlinking with replication, gene transcription and cell cycle checkpoints to promote cell survival and normal regulation of cellular functions after DNA damage, the repair system represents a protective mechanism that ensures the maintenance of genomic integrity during the cell life; when unrepaired or incorrectly repaired, DNA damage can cause a loss of genetic information, or, due to an uncontrolled accumulation of mutations, a genomic instability that results in the cell cycle arrest and cell death. Amongst fungal species, *Aspergillus nidulans* has been extensively studied with respect to metabolism, cellular development, and regulation, since the ability to genetically manipulate this organism, and combine genetic traits by sexual crossing, has been crucial for its pronounced role as genetic model organism. In 2004, Goldman and Kafer reviewed the history of *Aspergillus nidulans* as the object of studies focused on three different cellular processes now identified as essential components of the complex phenomenon of DNA damage response (Goldman and Kafer, 2004). Comparative tests conducted in *Aspergillus* mutants and the analysis of genetic control of their cell cycle, revealed key checkpoints that regulate every step to guarantee the completion of DNA replication and its repair before entry in mitosis. Overall, the possibility to visually distinguish specific aneuploids and other aberrations, identifiable by the segregation of heterozygous markers, made *Aspergillus* exceptionally suited for analysis of genetically unstable types, allowing for example the meiotic mapping of translocation breaks with recognition of the four types of partially aneuploid progeny being crucial, or malsegregation producing trisomics and other aneuploids (Kafer, 1977).

A stress-induced genome instability has been recently underlined, in lead studies focused on the adaptive mechanisms of fungal pathogens, as a key event during the onset of drug resistance: this probably allows the pathogen to promptly manage the continuous changes in the environment it encounters in the host, determining in many cases an increase of the microorganism surviving chance against the fungistatic or fungicidal activity of anti-fungal drugs (Galhardo et al., 2007). In this sense, investigations on heterochromatin structure and function in fungal model systems could serve as a road map to elucidate the role of chromatin in regulating genome plasticity in plant and animal fungal pathogens. Studies performed in various *Aspergillus* species revealed that genetic diversity associated with subtelomeric regions might be important for driving adaptation to different host niche environments, mainly due to its modulatory effect on secondary metabolites gene clusters; these findings are considered to be valid also in *A. fumigatus*, the major etiological agent of invasive pulmonary and cutaneous aspergillosis, whose successful infection largely depends on the ability of the fungus to overcome the cellular response in the surroundings of the infection site (in particular the activation of phagocytes), achieving to adapt to a multiplicity of host-niches environments (Buscaino, 2019 and reference therein).

Besides virulence characteristics, many aspects of the fungal morphogenesis have been proven to be regulated by chromatin remodeling: according to evidences obtained in *A. flavus*, in fact, the production of reproductive, dispersal or resistance structures (such as conidia and sclerotia) were demonstrated to be influenced by the methylation of specific sequences in the genomic DNA (Liu et al., 2012; Yang et al., 2016), as well as the regulation of small bioactive molecules, whose biosynthesis depends on specific gene clusters located throughout the genome and that are critical for the interaction of Aspergilli with other organisms, enabling filamentous fungi to successfully exploit environmental resources by modifying chemical diversity (Shwab et al., 2007).

Drug Resistance Runs Rampant

Genus *Aspergillus* contains a large number of both pathogenic and opportunistic species, that potentially cause mycosis in humans and animals: for example, *A. fumigatus* is responsible for the 90% of human fungal infections, followed by *A. flavus*, *A. terreus*, *A. niger* and *A. nidulans* species. Due to the mortality rate of Aspergillus-related allergic syndromes and invasive aspergillosis (that can range up to 90%), the escalation of fungal drug resistance is a growing concern in the human health context (Morgan et al., 2005). To achieve insight into the mechanism of action of antifungals resistance in *Aspergillus* species remains quite simple, as the occurrence of drug-resistant isolates is frequent and they can straightforwardly be studied. Besides the classical mechanisms that mediate the development of drug resistance phenomena, typically based on the modification of drug targets (owing to mutations which lessen drug-target interactions), the loss of drug effectiveness (due to increase in drug efflux or overexpression of drug targets) or metabolic bypasses (through the activation of compensatory mechanisms which abolishes the drug toxic effect), new mechanisms were recently observed in *Aspergillus* spp., including the emergence of simultaneous resistance to more than one class of drugs (Sanglard, 2016). Reviewing the literature concerning proteome changes in *Aspergillus* isolates exposed to antifungals and phytochemicals, it could be noticed that factors responsible to provide resistance seem to be mainly enzymes involved in cell wall remodeling, oxidative stress response and energy metabolism (Shishodia et al., 2019); over 70 proteins have been found up-regulated during interaction with different antifungal agents, while at least 26 showed to be affected, in their expression level, by more than two antifungal agents, suggesting a wider response. Globally, available data suggest that alterations in drug targets is the most common strategy for resistance against fungicides in Aspergilli; however, the role of extracellular matrix has been recently associated to the development of resistance in biofilm-forming fungi: the formation of matrix in biofilm structure has been hypothesized to sequester antifungal molecules and reduce the drug susceptibility *via* the activation of multidrug resistance protein that pumps out noxious compounds (as observed for specific efflux-pump in azole resistance and described by Rajendran et al. (2011)) and Rajendran et al. (2011), disallowing their diffusion

through fungal hyphae. This unexpected cue do not only offers possible reasons for treatment failure in aspergillosis cases, but, showing interesting absorption properties of fungal biofilm, might also suggest new applications for them.

Antifungal agents are also used in crop protection, to defend plants from pathogens attack and to preserve food/feed commodities from fungal decay. In particular, the control of mycotoxigenic fungi diffusion by the use of synthetic fungicides is still the most effective among the good agronomical practices, whose positive effects are appreciable both in field and during storage (Rose *et al.*, 2018). The problem of mycotoxins exposure of consumers raises a serious concern for animal and human health, worsened by the carry-over of certain toxins along the food chain (International Agency for Research on Cancer, 1993; Fanelli *et al.*, 2004). The global warming will impact on disease and pest invasion of staple crops; therefore, a dramatic increase of mycotoxins contamination driven by the climate change is a realistic scenario (Medina *et al.*, 2015). On the other hand, in order to limit the emergence of acquired resistance in relevant fungal species is imperative to reduce the use of antifungals in the environment, identifying at the same time new generation fungicides effective against resistant isolates. Screening based on the use of *Aspergillus flavus* for the assessment of the fungistatic or fungicidal activity of newly synthesized compounds have been developed (Zani *et al.*, 2015; see “Relevant Websites section”): through the development of a simple and high-throughput procedure for the evaluation of mycelium growth and mycotoxin production, associated with toxicity, genotoxicity and *epi*-genotoxicity assays in human cell and plant model systems, a battery of over 200 new compounds was tested; data were organized in a Q-SAR database, that correlating chemical structures and biological/toxicological activities is projected as a tool for users searching for specific bioactives, or to simply predict the potential effect of similar compounds.

What About the Contribution of *Aspergillus* in the Comprehension of Cell Biology and Eukaryotes Development?

Fungi have been long time used to study the progression and regulation of mitosis, meiosis or organelle movement, revealing valuable insights into these evolutionarily conserved processes and emphasizing the correlation between cell biology and differentiation processes in eukaryotes. *Aspergillus* development and morphogenesis studied at a molecular level endorsed the individuation of genes specifically involved in the regulation of basic cellular events: using temperature sensitive *nimA* mutants of *A. nidulans*, Lies and co-workers suggested the presence of a novel, late G₂ checkpoint, that prevent the inappropriate entry into mitosis by the control of the activation of BIMAAPC3, an anaphase promoting complex/cyclosome (APC/C) component (Lies *et al.*, 1998). *A. nidulans* also provided important cues about dynamics of actin during cytokinesis, since its septation process superficially resembles cytokinesis in animal cells; studies performed in the filamentous fungus demonstrated that an intact mitotic spindle is required for actin ring formation, and that a mitotic checkpoint may prevent further progression of cytokinesis in the absence of an intact mitotic spindle (Bruno *et al.*, 2001; Momany Morrell-Falvey *et al.*, 2011).

The life of eukaryotes is, with few exceptions, characterized by developmental processes more or less involved in specific pathways of secondary metabolism, where the term “secondary”, introduced by Kossel in 1891, implies that primary metabolites are present in every living cell capable of dividing, while secondary metabolites are present only incidentally and without any central significance for the organism. Actually we know that’s not true, or, at least, it could be true with this restricted interpretation: a large number of physiological, morphological and developmental processes have been demonstrated to be linked to (when not depending on) specific secondary metabolic pathways. Compared with primary metabolism reactions, which are highly conserved over highly different organisms, a huge diversity is observed in secondary metabolism pathways at the level of species, organs, tissues, and single cell, and even at different developmental stages; the environmental advantages represented by the availability of a wide range of extraordinarily different compounds from secondary origin and its high level of catalytic promiscuity are thought to be due to its recent divergence from primary metabolism and to a weaker selection pressure than to primary metabolic enzymes (Tokuriki *et al.*, 2012). A modern conception of “secondary metabolites” defines them as bioactive molecules of low molecular weight that are not specifically required for growth of the organism, but aid survival in harsh conditions, providing resistance against desiccation and UV-derived stress (Nguyen *et al.*, 2013) and improving competition with other organisms: namely, an arsenal of small and versatile compounds that, impacting the environmental fitness, necessarily interact with primary processes.

In this sense, *Aspergillus* spp. embody one of the major examples of variety and diversity (Romsdahl and Wang, 2019), representing excellent model systems for research in metabolomics and comparative phylometabolomics, as comparative studies of conserved and unique metabolic pathways will help in the annotation of metabolites as well as provide important new targets of investigation in biology, biomedicine and industry. For example, the genomic analysis on *A. oryzae*, an important industrial mold used for fermentation purposes, indicated in this specie a large number of putative biosynthetic genes for secondary metabolites, even if many of such compounds have not been identified yet: through the screening of a gene-disruption library of transcription factors including chromatin-remodeling agents, two genes were found to be involved in similarly altered patterns, contributing to a better understanding of secondary metabolites production not only in *A. oryzae*, but also in other fungal species (Shinohara *et al.*, 2016).

Some secondary metabolites are known to overcome the host immune system by affecting immune cell function or by shielding the pathogenic fungus against host defense, or being useful to acquire essential, scarce cofactors, as well demonstrated by the plethora of studies on the human pathogen *A. fumigatus* (Raffa and Keller, 2019). Consistently, the increased interest in secondary metabolites has triggered a number of genome sequencing projects to investigate as well as elucidate their biosynthetic pathways, leading to the conclusion that the number of secondary metabolite gene clusters (SMGCs) greatly outnumbers characterized compounds, challenging current methods to dereplicate and categorize this amount of gene clusters on a larger scale. A detailed analysis has been conducted on *Aspergillus* section *Nigri* to investigate species similarities on the SMGC content level and genetically dereplicate gene clusters: using secondary metabolite gene cluster networks, SMGCs were categorized across genomes

into SMGC families, allowing to highlight, through the dynamics of secondary metabolism in section *Nigri*, that SMGC diversity within the section has the same magnitude as within the genus; when validated to find gene clusters for analogous compounds in newly sequenced genomes, this particular genome analysis resulted successful to predict of the gene cluster responsible for biosynthesis of malformin, an enhancer of anti-cancer drugs, in 18 strains (Theobald *et al.*, 2018).

To date, despite the importance of the metabolomic investigation, there are few databases that provide complete, species-specific information, and even fewer on secondary metabolism and secondary metabolites of biological relevance; with this goal, the open resource A2MDB *Aspergillus* metabolome repository (*Aspergillus* Secondary Metabolites Database; see “Relevant Websites section”) has been recently created: it collects experimental metabolomic data, cataloged and annotated with literature information, and reports over 800 unique non-redundant secondary metabolites (including mycotoxins) derived from 675 *Aspergillus* species (Vadlapudi *et al.*, 2017). Together with a phylogenetic representation of over 2500 strains and 150 microscopy images of several *Aspergillus* species, the database provides a compilation of 44 secondary metabolic pathways and 100 cellular targets of secondary metabolites, along with all the available molecular docking models of metabolite-target protein interactions.

The Evolutionary Dynamics Explained

Countless are aspects of cell biology under the magnification lens of the evolutionary investigation, but phosphorylation is probably one of the most intriguing, since approximately the 30% of cellular proteins are phosphorylated (Cohen, 2000). Potentially interesting either the DNA or the protein level, phosphorylation may exert different physiological implications for the cell: phosphate groups can change the structural backbone of the DNA, serving as regulators for epigenetic control through the transient activation of defined phases of gene transcription such as initiation, elongation and termination; contextually, as for other post-translational modifications, protein phosphorylation is commonly required for the correct carrying out specific function, whether structural or catalytic. Intra- and intercellular signaling pathways also are affected by the phosphorylation status of the cell, without considering a huge amount of biochemical and biophysical aspects occurring in the cell cycle and involved in the development and reproduction. Hence, questions about the role of phosphorylation/dephosphorylation as a possible trigger for the evolution of eukaryote organisms reasonably would arise: did the natural selection force specific phosphosites over others? How this selection could have been determined, among all the available protein motifs potentially suitable as sites for inserting a phosphorus atom? Could the phosphorylation patterns be used for phylogenetic purposes, aimed for example at clarifying the species origin? While to date we are still lacking a real phylogenetic understanding of phosphosite evolution, at the same time the question could be faced from another side of the coin, that is represented by the analysis of the enzymatic ensemble responsible for the kinase cascades inside the cell environment, since phosphoregulatory networks evolve by the gain or loss of protein-protein interactions, either by changes to substrates, or by changes to kinase specificity. A functional characterization of the kinome and its control was conducted, in 2011, in the plant pathogen *Fusarium graminearum*: authors generated deletion mutants for 96 protein kinase genes, assaying all the resulting knockout individuals for changes in 17 phenotypes (including growth, reproduction, stress responses, and plant infection). At least half of the mutants resulted non-pathogenic or significantly reduced in virulence, while 26 were blocked in ascospore production, that represent the primary inoculum for wheat scab induced by *Fusarium* species. A number of kinase genes that proved to be unessential for hyphal growth were instead suggested to encode novel fungal virulence factors. (Wang *et al.*, 2011). De Souza *et al.* reviewed and extended in *A. nidulans* the characterization of filamentous fungal kinases from a phylogenetic perspective; their final report underlined kinases in regulating ribosomal biogenesis, mRNA splicing and unfolded protein response, as well as revealing previously unknown roles for kinases in the regulation of hyphae elongation and septation, polarized growth, cell cycle, development, secondary metabolism, DNA damage response, and the cellular response to osmotic stress (De Souza *et al.*, 2013).

Once more in *A. nidulans* it was possible to identify both direct and indirect targets of protein kinase A (PKA) phosphorylation, as well as genes whose expression relies on its functionality; besides providing a broad overview of the PKA regulatory network in a model filamentous fungus, these results would facilitate detailed functional investigation of PKA phosphorylation events and their role in growth and development (Ribeiro *et al.*, 2019).

The human pathogen *Aspergillus fumigatus*, leading infectious killer in immunocompromised patients, served to define an evolutionarily conserved novel mode of regulation of calcineurin, a calmodulin CaM-dependent protein phosphatase, by phosphorylation, thanks to the study of a serine-proline rich region (SPRR) located in a region absent in humans; findings suggest the possibility of harnessing this unique SPRR for innovative antifungal drug design to combat invasive aspergillosis (Juvvadi *et al.*, 2013). The phosphorylation status of calmodulin was also demonstrated to be critical for the secondary metabolism of *Aspergilli*: the first study on the phosphoproteome of *A. flavus* demonstrated that phosphorylation is tightly connected with the biosynthesis of aflatoxin through the regulation of the acetyl-CoA flux, and provided the first evidence linking the phosphorylation of MAP kinase with growth, conidial production and sclerotial formation in this phytopathogenic species (Ren *et al.*, 2016).

Spilling the Beans on the Antioxidant Potential of Bioactives

Oxygen, the essential element for life as we know on Earth, triggered the evolution of organisms from single entities to specific cells within multicellular systems; studies show how organisms containing the most different cell types evolved following the increase of atmospheric oxygen, giving rise to the complex life we can witness today (Hedges *et al.*, 2004). But the price for an aerobic life is

the inevitable oxidation of molecules: by offering an incredible advantage for cellular energetics by supporting high-efficiency production of ATP, the oxygen-based respiration forces in turn to deal with reactive forms (Reactive Oxygen Species) such as superoxide, hydroperoxides, hydroxyl radicals, that promote the progression of oxidative stress at a cellular level. In eukaryotic cells, oxidation and associated events are contributing-cause of aging in general, and in particular of many human diseases; atherosclerosis, Parkinson's and Alzheimer's diseases, skin disorders and cancer are outstanding examples. Hence is not surprising the rampant use of antioxidants in order to achieve and preserve optimal health: nutraceuticals and food supplements are frequently fortified with antioxidants compounds from both synthetic and natural origin, and cosmetic Companies compete in claiming, in their formulation, the presence of bioactives which promise to protect the consumers from undesirable effects of ROS. By definition, "antioxidant" is every substance that, at low concentrations, prevent or retard the oxidation of oxidizable biomolecules, such as lipids, proteins and DNA (Halliwell and Gutteridge, 2007). Actually, plants are the main source of naturally-derived molecules used with these purposes, partially due to the biological ability of secondary metabolites (such as phenolic compounds, vitamins C and E, and carotenoids) to be potent free radical scavengers: anti-inflammatory, antimicrobial, antiviral, antiallergic activities, as well as inhibition of lipid peroxidation, have been proven (Ndhlala *et al.*, 2010 and references therein).

Driven by the need for more effective, less toxic and cost affordable antioxidants, a great number of *in vitro* methods have been developed to measure the efficiency of natural compounds either as pure compounds or as plant extracts. As these bioactive are predominantly reducing agents, singlet oxygen quenchers or metal chelators, *in vitro* classical techniques are chemical-based methods, characterized by high speed and sensitivity, and historically grouped according to the mechanism of action: Oxygen Radical Absorbance Capacity (ORAC), Total radical trapping antioxidant potential (TRAP) and β -carotene bleaching methods rely on hydrogen atom transfer reactions, while Trolox Equivalent Antioxidant Capacity (TEAC), Ferric Reducing Antioxidant Power (FRAP), α , α -diphenyl- β -picryl-hydrazyl Radical Scavenging Assay (DPPH), Total Phenol Assay and others are based on electron transfer reactions.

However, the complex nature of phytochemicals, which effect often seem to be a result of synergism/cooperation with other compounds, the objection that *in vitro* chemical assays are based on free radicals usually not found in living cells, and the comprehension that the complexity and heterogeneity of biological systems do not allow anything to work in isolation (if a redox reaction takes place, then something else must occur to balance electrons in the cell environment) (Shen *et al.*, 2007), supported the ever increasing criticism about the real predictability of such inferred antioxidant capacity. Overall the dichotomic behavior of antioxidants in terms of incoherence between *in vitro* and *in vivo* activity, that was tentatively explained with the heterogeneity of biological systems and the interactions between scavengers and surrounding molecules in the cell environment, has had important implications for updating the current strategies for screening and designing antioxidant drugs. Additionally, not all methods and antioxidant species are compatible: as a consequence, the same compound can yield dissimilar results in different assays. The complementary use of methods employing different mechanisms of action could be recommended to evaluate plant extracts or pure compounds, but eventually, for bioactive purposes, *in vivo* models remain extremely desirable: in fact, even though authors usually find a good degree of correlation between *in vitro* scavenging activity and the total phenolic content, the association between *in vitro* and *in vivo* methods is still debatable; the huge amount of data obtained by merging *in vitro* and *in vivo* results is dotted by often controversial results, since some research outcomes might led to the persuasion that the majority of so-called antioxidants exist as legendary biomolecules.

Whenever possible to perform, *in vivo* investigations are undoubtedly more reliable to assess both potential for interaction as well as mechanisms by which various natural products may interact, for example, with cellular enzymes, membrane transporters or metabolic pathways (Granato *et al.*, 2018). To date, the existing knowledge about the responsible phytochemicals for the biological activity, their mechanisms of action and even the occurrence of biochemical inter-relations, is substantially scarce, while one of the main important cues of studies on oxidative stress is to define – at the molecular level – the cellular processes involved in cell sensing, signaling, transduction and the adaptive responses.

Compounds with antioxidant properties frequently display also interesting biological activity, such as antifungal potential and modulatory effects on fungal secondary metabolism (Palumbo *et al.*, 2007; Gacem *et al.*, 2019), so that, an easy-to-handle specie which developmental and metabolic features remain well known is a good candidate to become an excellent model system, as well as the possibility of using high-throughput small-scale *in vivo* model systems to predict a possible antioxidant-related biological activity of compounds (pure or in mixture) and natural extracts such as botanicals before their medical application is therefore desirable (Reddy *et al.*, 2010). Studies comparing antioxidant potential and mycelium growth and/or development in *Aspergillus* spp. date back to decades. Reactive oxygen species (ROS) in particular, and their reactive products such as peroxidized lipids, have been long time associated with fungal stress responsive signaling and secondary metabolite production, stimulating *in vitro* the accumulation of aflatoxin by *Aspergillus flavus* mycotoxigenic strains; conversely, many compounds with scavenging properties exert a containment effect on the biosynthesis of the toxin (Jayashree and Subramanyam, 2000; Passone *et al.*, 2005), mainly through the activity of enzymes involved in oxidative stress alleviation (catalase, glutathione peroxidase, superoxide dismutase); additionally, antioxidant compounds inhibiting aflatoxins have been demonstrated to frequently impair also sclerotia development, probably due to the presence of several, shared regulatory steps (Fountain *et al.*, 2016). The response to redox balance alterations of sclerotia metabolism and aflatoxin production, that was suggested to have been evolved to cope with an excess of intracellular ROS produced in the late phase of growth during morphological and metabolic transitions, have been profitably exploited in recent years to evaluate the antioxidant capacity of both single molecules and natural extracts with the attempt to predict, through a microbial-based *in vivo* assay, biological activities with further potential application in different fields. In this regard, *A. flavus* has been used to investigate a wide number of plant extracts (Reddy *et al.*, 2009; Degola *et al.*, 2019) and newly synthesized molecules (Rogolino *et al.*, 2017), and the development of a high-throughput methodology, based on micro-cultures in multiwell plates and a fluorescence-based, real-time detection of aflatoxins directly in the culture medium have significantly

increased the performance of *A. flavus* (and related species) as model system for such purposes (Degola *et al.*, 2017; Bisceglie *et al.*, 2020; Orsoni *et al.*, 2020).

A Stairway to System Biology

We previously disserted about the great contribution that research on *Aspergillus* is providing to our understanding of eukaryotic primary and secondary metabolism, control of gene regulation by external environmental factors, cell cycle and development; from a clinical perspective, one of the most relevant examples of the value of *Aspergillus* as a model could be found in the identification of the genetic basis of the human metabolic disease alkaptonuria, determined by genetic errors in tyrosine/phenylalanine metabolism: taking advantage of the ability of *Aspergillus* to grow in presence of any single amino acid as sole carbon source, researchers succeeded in identifying the fungal enzyme and, by using its amino acid sequence, to isolate its human, disease responsible counterpart (Fernández-Cañón *et al.*, 1996). Besides infinite, single examples, the availability of such enormous amount of data obtained in *Aspergillus* species through omics technologies (like genomics, transcriptomics and proteomics) will allow a more comprehensive understanding of genetic traits governing desirable properties, from enzymes production to the pathogenic potential, easily converging in an advanced tool for the systems biology research; in this sense, CRISPR/Cas9 technology will accelerate data generation, speeding up genetic research in the Aspergilli field, and, in turn, an increase in systems biology targeted exploration (Nødvig *et al.*, 2015). The efficiency of targeted genetic manipulation has already proved to enable the assessment of a large number of modifications in a high-throughput manner; therefore, by exploiting this gain in strain development will speed up the elucidation of pathways both in primary and secondary metabolism, as well as enabling the development of genome-wide screens (*e.g.*, knockout libraries) as has been performed in other model systems (Fuller *et al.*, 2015; Katayama *et al.*, 2016).

The increase in throughput of data generation will lead to future challenges in the data handling, integration and interpretation, but today it certainly offers the possibility to acquire a paramount overview of biological knowledge as never before: the consciousness that no element of a cell is an island, but everything is necessarily connected to the rest, has carried systems biology to a holistic approach, in the attempt to conceive (and thus comprehend) life as multilevel systems that have co-evolved, instead of the simple sum of its parts. The recent publication of the genome sequences of several *Aspergillus* species, has, alongside the increase of reductionist studies, been a catalyst for the application of systems biology approaches to this group of fungi; more than 50 laboratories around the world are currently devoted to *Aspergillus* research, as well as various are the websites dedicated (see “Relevant Websites section”): this new analytical and computational tools have been designed and a systems biology approach has been applied to a wide range of issues.

Over all species belonging to its genus, *Aspergillus niger* probably possesses the most impressive variety of high-yield products, holding the potential to become an even more versatile cell factory platform for industrial microbial purposes and bio-based economy in the future; thanks to the availability of its genome sequence, a high potential for the mining of new products has been suggested, but only an integration of a full genome-scale metabolic network with genomic annotation will allow system biology applications. With this ambition an accurate model has been recently created on the basis of a complete bibliomic survey of the literature on *A. niger*: a complete catalog of all reported intracellular enzymatic activities was used to build a comprehensive database of the entire metabolic network, providing a link between reactions, genes and scientific literature and, hence, being useful for several uses, such as identification of targets for metabolic engineering, interpretation of transcription data and identification of regulatory features and metabolic flux analysis, for the systemwide examination of data in a metabolic context (Andersen *et al.*, 2008). To date, achievements in the field has definitely highlighted the impact of *Aspergillus* systems biology on industrial biotechnology, making possible to implement systems biology tools to advance metabolic engineering.

Introduction

Protein represents the molecular product of the genes as the final step of the translation process, whose expression changes according to cellular and environmental conditions. The term “Proteomics” was first coined in 1997 (James, 1997) because of its assonance with genomics, the study of genes, and it was initially defined as a technique for global characterization of all the components of the proteome, which in turn represents the entire set of proteins expressed by an organism.

A better definition of the term Proteomics includes the large scale study of the complete protein asset of a cell, tissue, or organ (Tyers and Mann, 2006; Pandey and Mann, 2000), which is expressed in a particular moment under different environmental conditions (Graves and Haystead, 2002), together with its cataloging (descriptive proteomics), its abundance (quantitative proteomics), genotype-dependent variations (population proteomics), the implication in the development and environmental responses changes (differential or comparative proteomics), post-translational modifications (PTMs), and interactions with other proteins and molecular entities (interactomics) (González-Fernandez and Jorrín-Novo, 2012).

The proteome of an organism represents a dynamic system, with significant variations among different cells and tissues, and development time. During the translation process, not all the mRNA is usually converted into proteins, and the mRNA levels are not always correlated to protein content (Rogers *et al.*, 2008; Zhang *et al.*, 2010; Vogel and Marcotte, 2012). As a result of the differential gene expression among cells and tissues, proteomics could offer a fingerprint of cell, tissue and organ state in a particular time frame.

Proteomics could be used to complement other functional approaches (Tyers and Mann, 2006), including transcriptomics (the study of mRNA), genomics (the study of genes) and metabolomics (the study of metabolites); the integration of all these approaches is called *system biology* (Horgan and Kenny, 2011), representing the study of biological systems whose behavior cannot be reduced to the linear sum of their parts' functions. In this view, proteomics represents a reliable technique due to several aspects since proteins are directly related to function or phenotype of biological systems (Bhadauria *et al.*, 2007). They go through a series of modifications, also called post-translational modification (PTM), which affects their functions. Over 200 forms of PTM are currently known (Zhang *et al.*, 2010; Virág *et al.*, 2020), including phosphorylation, methylation, glycosylation, and sulfation. Historically, single proteins could be separated by a wide range of techniques, like chromatographic technique enzymatically characterized and subjected to N-terminal or partial amino acid sequence analysis (Doyle, 2011).

Quantitative proteomic analysis can be classified into two groups, either gel-based or gel-free methods as well as “label-free” or “label-based” (Fig. 1); the latter can be further subdivided into several labeling approaches such as chemical and metabolic labeling (Abdallah *et al.*, 2012).

The gel-based approach is mainly based on the use of SDS-PAGE (Sodium Dodecyl Sulfate - Polyacrylamide Gel Electrophoresis) or the 2-DE (two-dimensional electrophoresis). SDS-PAGE is a common technique used for protein separation based on their molecular weight, which was firstly developed by Laemmli (1970).

The 2-DE technique allows the separation of proteins based on their molecular weight and isoelectric point (pI) to resolve complex protein leading to high-resolution fingerprint. Since the publication of O'Farrell (1975), the 2-DE technique represents a powerful tool for the analysis and detection of proteins from complex biological sources. The introduction of immobilized pH gradient (IPGs) instead of the carrier ampholytes (CA) for the first dimension has been allowed to overcome most of the limitation of the 2-DE technique, including reproducibility, resolution, and ability to separate very acidic/basic proteins (Görg *et al.*, 2004). The 2-DE gel images are then acquired and used for quantitative analysis through imaging software for measuring spot intensities (Dowsey *et al.*, 2003).

Nevertheless, some shortcomings still affect the use of this technique, limiting its application. These issues include a limited dynamic range of detection, the exclusion of some classes of proteins (e.g., too acid or basic proteins), as well as the limitations to soluble and abundant proteins (Görg *et al.*, 2009; Chevalier, 2010). 2-DE also represents labor-intensive, which is challenging to automatize (Wang *et al.*, 2005).

In this view, the gel-free approach has progressively replaced the gel-based approach in many research areas due to several advantages, including reproducibility and the ability to study specific classes of proteins (Abdallah *et al.*, 2012; Jorrín-Novo *et al.*, 2015). Initially, these approaches were used as a replacement for 2-DE (Abdallah *et al.*, 2012). However, most recent proteomic papers were only based on gel-free analysis or used both approaches as complementary (Jorrín-Novo *et al.*, 2019). Gel-free studies consist of two main steps peptide separation and MS identification; moreover, also intact proteins can be analyzed using a gel-free approach (Tran *et al.*, 2011; Toby *et al.*, 2016).

The first step includes a wide range of techniques, like the Ion-exchange chromatography (IEC), the reverse phase chromatography (RP), the two-dimensional liquid chromatography (2D-LC), and the off-gel electrophoresis (OGE) (Abdallah *et al.*, 2012). After separation, proteins could be tagged using chemical and metabolic labeling, which represented a significant development for large

Fig. 1 Schematic overview of a proteomic workflow basing on different approaches (gel-based and gel-free) and MS analysis of intact protein (top-down) or peptides (bottom-up). Image modified from the original one Jorrin-Novo, J.V., Pascual, J., Sánchez-Lucas, R., *et al.*, 2015. Fourteen years of plant proteomics reflected in proteomics: Moving from model species and 2DE-based approaches to orphan species and gel-free platforms. *Proteomics* 15, 1089–1112. doi:10.1002/pmic.201400349.

scale proteomics. Chemical labeling includes some techniques like the isotope-coded affinity tag (ICAT) (Gygi *et al.*, 1999) and the Isobaric Tags for Relative and Absolute Quantification (iTRAQ) (Abdallah *et al.*, 2012). The ICAT represents one of the first developed labels (Wiese *et al.*, 2007). It consists of marker probes composed by three elements, a chemically reactive group that binds the side chain of specific amino acid in the sample (e.g., iodoacetamide binds the cysteine residues), an isotopically coded region (heavy and light), and the tag (e.g., biotin) for the affinity-based purification (Gygi *et al.*, 1999; Colangelo and Williams, 2006). The iTRAQ is a newer chemical labeling method more suitable for labeling peptides rather than proteins. It consists of isobaric tags, that bind peptide in protein digest via free amines on N terminus and the side chain of lysine residues. The protein pool can be labeled and analyzed simultaneously. The use of isobaric tags does not shift the mass under Mass Spectrometry (MS) analysis leading to an increased sensitivity due to the cumulative signal on the same peptide from different samples (Unwin, 2010). Metabolic labeling is based on two main techniques: stable isotopic labeling with amino Acids in cell culture (SILAC) and N isotopic labeling. Both approaches are based on the incorporation of isotopes in vivo, with some differences. In SILAC, isotopically labeled amino acid is added to the culture medium to differentiate two populations (one labeled and one non-labeled). The efficiency of SILAC techniques depends on the organism's autotrophy, so it is less suitable for plants, cell cultures, and some types of unicellular organisms. However, it can be used for the analysis of fungal pathogen species (Jang and Kim, 2018). N isotope labeling uses ^{15}N -labeled inorganic salt and provides a better incorporation efficiency respect to SILAC (98% respect to 70%–80% in cell cultures), and it is more suitable for quantitative proteomics in plant sciences (Abdallah *et al.*, 2012).

Mass spectrometers are instruments able to analyze ionized analytes in the gas phase. Three main parts compose them, an ion source that produces ion analytes, a mass analyzer that separates them based on their mass-to-charge ratio (m/z), and a detector that records the number of ions at each m/z value (Aebersold and Mann, 2003). The development of ion sources was catalyzed by two technical breakthroughs in the late 1980s: the two-ionization methods Electrospray Ionization (ESI) and Matrix-Assisted Laser Desorption/Ionization (MALDI). Because of the lack or minimal extent of analyte fragmentation during the ESI and MALDI processes, they are also referred to as “soft” ionization methods (Aebersold and Goodlett, 2001).

The analyzers are composed of several types, which can also be combined to form tandem mass spectrometers. The most commonly mass spectrometers used in Proteomic analysis used are the ion Trap, the Time-of-Flight (TOF), the quadrupole mass spectrometer, and the Orbitrap, where the latter represents the newest mass spectrometer. It is also possible to combine different analyzers, forming the so-called hybrid instruments. These high-resolution instruments become available in the last years, with high-resolution mass analyzers such as the LTQ/FT, LTQ-Orbitrap and quadrupole-TOF (Q-TOF) allowing to substantially increased the number of proteomics applications in biological research (Gregorich *et al.*, 2014; Yates *et al.*, 2009; Zhang *et al.*, 2010).

The MS-based proteomics strategies could also be grouped into two main groups based on protein status, namely “bottom-up” and “top-down” each of which presents advantages and disadvantages (Gregorich *et al.*, 2014). In the bottom-up approach, MS analysis is performed on peptides generated by proteolytic digestion. A classic bottom-up approach provides that extracted are subjected to enzyme-based proteolytic digestion (e.g., using a serine protease, trypsin) or are first separated by polyacrylamide gel (2-DE or SDS-PAGE) followed by in-gel digestion (Aebersold and Mann, 2003; Gregorich *et al.*, 2014). In the latter case, gel bands are excised, digested, and separated by reverse-phase LC.

When gel separation does not occur, the peptide mixture can be separated into two dimensions, on the base of the charge (e.g., using cation exchange column) and then on their hydrophobicity (Steen and Mann, 2004). Shortcomings of the bottom-up approach are mostly related to the significant number of peptides that entering the mass spectrometer at the same time, making it difficult to achieve full protein identification and increasing the LC-MS variability (Zhang *et al.*, 2010; Cargile *et al.*, 2004).

In the top-down approach, proteins are analyzed without any proteolytic digestion (Siuti and Kelleher, 2007), leading a characterization of intact proteins from complex biological systems. Intact proteins are then directly introduced into the mass spectrometer, where both their intact and fragmented ions masses are measured (Catherman *et al.*, 2014).

This approach preserves all the information on the native status of protein, with the potential to identify a more significant fraction of protein sequences, including the ability to locate and characterize PTMs (Zhang *et al.*, 2010) or the identification of protein-protein interactions (Aebersold and Mann, 2003; Catherman *et al.*, 2014). Furthermore, when using top-down approaches, time-consuming steps like protein digestion are no longer necessary (Konijnenberg *et al.*, 2015). The disadvantages linked to top-down approaches are based on the fact that this approach is very demanding in terms of the instrumental setup (Schneider and Hall, 2005; Armirotti and Damonte, 2010), both in terms of cost and resolving power and sensitivity; other limitations including the difficulty to detect highly charged proteins and the coelution of intact proteins after LC separation that also complicates MS spectra (Cupp-Sutton and Wu, 2020).

Despite these limitations, the late developments have expanded the field of application of top-down proteomics, mostly lead to capable of proteoform profiling across multiple samples with high-throughput approaches (Toby *et al.*, 2016) through the successful development of new high-resolution mass spectrometers (e.g., quadrupole time-of-flight, Q-TOF) (Chen *et al.*, 2018).

Therefore, also considering the broad range of proteomic studies in fungal research, this chapter will mainly focus on two research fields, mycorrhizal and pathogenic fungi, which are growing in importance due to many economic and environmental aspects.

Ectomycorrhizal and Endomycorrhizal Fungi

In nature, organisms belonging to different Kingdoms may develop intimate relations with beneficial partners. Such kind of relationships are usually referred to as a ‘mutualistic symbiosis’. Among them, the association of plants with nitrogen-fixing rhizobia and with mycorrhizal fungi are well known (Markmann and Parniske, 2009; Smith and Read, 2008). Different types of mycorrhizal symbioses can be distinguished through the interaction method developed by the fungal partner (Fig. 2): in the so-called ‘ectomycorrhizae’ (ECM), the fungal hyphae remain outside the plant root cell, while in the ‘endomycorrhizae’ – including orchid, ericoid and arbuscular mycorrhiza (AM) – the fungal hyphae can enter into the plant cells (Balestrini and Lumini, 2018).

ECM represents a resource from many points of view; their role in the forest ecosystem was mainly related to the fact that they played the central role in the nutrient cycle and reforestation process. It is undoubtedly essential, but the economic value of their fruiting bodies is equally relevant. The economic and agronomic relevance of some ECM species like those belonging to the *Tuber* genus has, over the years, led to the creation of numerous scientific works focusing on the analysis of the protein structure. These works, evaluating the proteomic profile in one or more stages of the development cycle, aimed to clarify the complex biochemistry linked to this genus. Most of the studies concerning the species belonging to the genus *Tuber* focused on the mycelial phase and in the fruiting body, known as truffles, using a wide range of techniques for the purification and analysis of proteins. Many of the studies published to date almost concern three species belonging to the genus *Tuber*: *Tuber borchii*, *T. melanosporum*, and *T. magnatum*.

In *T. borchii*, the fruiting body proteome was firstly analyzed by SDS-PAGE and compared with other species of the same genus, *T. magnatum*, *T. dryophilum*, and *T. puberulum* and highlighting the presence of differences in electrophoretic patterns (De Bellis *et al.*, 1998). In the same work, a protein linked to a very abundant electrophoretic band weighing 12 kDa was identified. Mass spectrometry analysis led to identifying this band as the TBF-1 protein, absent in the other species analyzed, but subsequently also

Fig. 2 Representative illustration of root colonization and related structures in ectomycorrhiza and endomycorrhiza (arbuscular mycorrhiza). Image modified from the original one Bonfante, P., Genre, A., 2010. Mechanisms underlying beneficial plant–fungus interactions in mycorrhizal symbiosis. *Nat. Commun.* 1, 1–11.

identified in *T. dryophilum* (Agostini *et al.*, 2000). Subsequent studies based on hemagglutination and inhibition assays have shown how this protein, present in the unripe and ripe fruit bodies but not in ectomycorrhizal roots, represents an essential lectin in bacterial colonization process as it can selectively bind the exopolysaccharides produced by ascoma-associated bacteria like *Rhizobium* spp. (Cerigini *et al.*, 2008).

T. borchii was then analyzed to evaluate changes in the protein profile concerning the maturation stage of the carpophore (Pierleoni *et al.*, 2004), while the mycelial phase was analyzed extensively by evaluating the variations after thirty days of growth in a liquid substrate (Vallorani *et al.*, 2000) through analysis of two-dimensional electrophoresis (2-DE). In a subsequent work by the same working group (Vallorani *et al.*, 2002) the 2-DE analysis approach was used to characterize the NADP-glutamate dehydrogenase protein, reporting that the sequence of this protein was very similar to others found in different species of fungi, such as *Neurospora crassa* and *Penicillium chrysogenum*, and that was also expressed in the symbiotic phase. A recent publication of the genome of several Pezizomycetes (Murat *et al.*, 2018), where *T. magnatum* and *T. aestivum* genomes were released, has undoubtedly brought new information useful for defining the *in silico* proteome of these species. In the case of *T. magnatum*, proteomic studies have mainly dealt with identifying specific proteins related to fruiting bodies collected from different environments to prevent fraud related to the high commercial value of the product (Vita *et al.*, 2013, 2020).

The release of the *T. melanosporum* genome dates back in 2010 (Martin *et al.*, 2010), and the information obtained was useful to improve the level of protein identification for proteomic related studies. A detailed proteomic analysis of *T. melanosporum* fruiting bodies (Islam *et al.*, 2013) was performed using a combined 1D and LC-MS/MS approach leading to the proteomic characterization of 836 truffle proteins.

The relationship of mutual symbiosis between the host plant and the fungal partner was also addressed in other ECM fungi, like those belonging to the genus *Terfezia*. Proteomic analysis *Terfezia clavaryi* leading to the identification of a catalase protein, the *TcCat-1*, which is involved in the mycorrhizal colonization process (Marqués-Gálvez *et al.*, 2019). The authors identified high levels of this protein only in mature mycorrhiza, suggesting as its production seems necessary for fungi to elude host defense, including the production of ROS compounds as in some specific stress conditions. Protein profile *T. clavaryi* was also analyzed by SDS-PAGE by identifying the presence of a prevalent protein band at 18–20 kDa (Ammarellou, 2007), as previously identified in *T. borchii* fruiting body analysis (De Bellis *et al.*, 1998).

Proteomic studies were also conducted on other ECM, like those belonging to Basidiomycota. Three isolates with *Pisolithus tinctorius* different degrees of ability to induce mycorrhiza (null, moderate, and high) were inoculated on *Eucalyptus grandis* plants using a 2-DE approach. The isolate not able to induce mycorrhizal interaction do not affect the root protein pattern, whereas aggressive mycobionts induce severe alteration in protein expression (Burgess *et al.*, 1995). The same fungal species was also employed to identify cell surface proteins involved in the early stage of ectomycorrhiza symbiosis. After inoculation in *Eucalyptus globulus*, the biosynthesis of cell wall proteins was analyzed using a 2-de approach, identifying both in host plant and mycobiont a novel class of protein of 31–32 kDa named SRAPs (symbiosis-regulated acidic polypeptides) involved in the primary ECM colonization step (Laurent *et al.*, 1999).

Further study of *P. tinctorius* was assessed between mycorrhizal and nonmycorrhizal cork oak plants (Sebastiana *et al.*, 2017) using a 2D-Differential in-gel electrophoresis (DIGE) coupled with MALDI-TOF/TOF tandem mass spectrometry approach. Results

showed as no difference was detected at a foliar level, whereas 42 spots were identified as differentially regulated in roots. The MS analysis allows to identify 34 unique oak proteins, where those related to carbohydrate and energy metabolism, protein folding/ assembling, cell wall re-enforcement, defense, cytoskeleton biogenesis, and soil phosphorus transport acquisition were down-regulated following mycorrhiza formation and, conversely, proteins related to the antioxidant defense system, nitrogen assimilation, membrane lipid transport/metabolism, and phosphorus transfer seems as upregulated.

Recently, several studies were focused on the analysis of extracellular proteins, also called secretome, which can be produced by ECM fungi during the early stage of the mycorrhizal symbiosis process.

Proteomic methods have also been applied in *Laccaria bicolor* to assess the analysis of extracellular proteome, also called secretome, produced in a growth medium by free-living mycelium (Vincent *et al.*, 2012). The analysis was performed using a combined approach based on 2-DE, and nLC-ESI MS-MS (tandem mass spectrometry) led to the identification of 224 proteins, among which enzymes involved in cell wall remodeling, as well as those involved in soil organic digestion, were founded. Secretome analysis was also performed on Brown-rot (*Gloeophyllum trabeum*), and white-rot (*Pleurotus ostreatus*) growth in a sugarcane base medium, where an SDS-PAGE approach coupled with LC-MS/MS allows to identify 199 and 63 extracellular proteins, respectively, including a wide range of cellulases and carbohydrate auxiliary proteins involved in lignocellulose degradation (Valadares *et al.*, 2019). Response to abiotic stress was also evaluated according to a proteomic approach. *Boletus edulis* proteome was analyzed under salt stress conditions using a 2-DE ESI Q-TOF MS/MS mass spectrometry approach. Twenty-two spots were selected based on bioinformatical analysis, and the MS analysis leads to the identification of sixteen proteins belonging to different metabolisms, including the biosynthesis of methionine and DNA repair (Liang *et al.*, 2007).

A multidisciplinary approach was applied to the basidiomycete fungus *Hebeloma cylindrosporum* for the study of the fungal exoproteome as well as the effect of the establishment of mycorrhizal symbiosis (Doré *et al.*, 2015). In this paper, transcriptomic data from RNA-seq experiments were performed by comparing transcription abundances in free-living mycelia and mycorrhizas with *Pinus pinaster* seedlings obtained under two different environmental conditions, glasshouse and in vitro.

Proteomic analysis was mainly used to study the exoproteome, and proteins released by fungal mycelia in growth media were extracted, separated through SDS-PAGE, and analyzed via LC-MS/MS.

Computational analysis was used to complement the experimental approach to clarify the consistency of *H. cylindrosporum* exoproteome, which includes at least 869 potential proteins, 641 predicted in silico, and 228 not predicted but identified experimentally. The functional classification of protein identified three major groups, each of which accounts for 17% of the total identified proteins; these three groups are represented by small secreted proteins (SSPs), carbohydrate-active enzymes (CAZymes), and peptidases. When only 10% of the most abundant proteins were considered, results based on the emPAI score highlights as the SSP represents the most representing group that accounts for 29% of the total proteins. Most SSPs proteins reported an unknown function; a possible explanation regards the role of these proteins that could mediate interaction with host plants and other biotic and abiotic environmental factors.

Transcriptomics data confirm the effect of both symbiosis and environment on the development of fungal transcriptome, with a prevalence of upregulated genes due to mycorrhizal formation and in vitro growth.

Further study was also conducted on the establishment of mycorrhizal symbiosis, aiming to detect the impact of these processes on plant leaf proteome. In the work of Szuba *et al.* (2019), proteomic analysis was performed using *Populus × canadensis* plants inoculated with two isolates of *Paxillus involutus* that differ on their root colonization rates. These isolated were called H (high mycorrhization level) and L (low mycorrhization level); uninoculated plants were used to deepen the effect of ECM fungus. The proteomic approach was also integrated with biometrical and biochemical analysis to assess the rate of root colonization and to detect any variation in nonstructural soluble carbohydrates (SC), starch, and leaf pigments as a consequence of ECM colonization on the host plant. Results of 2DE and MALDI TOF/TOF mass spectrometry analysis detect a significant difference in terms of protein profiles between leaves of inoculated and those related to non-inoculated poplars. The leaf proteome of plants inoculated showed differences of 9% and 7% for those treated with isolate H and L, respectively. Despite that, increased carbohydrate biosynthesis was not detected between inoculated and non-inoculated plants, with carbohydrate, carbon, and leaf pigment levels and plant biomass that does not change. The MS analysis of differentially regulated spots identified alterations in photosynthesis, with plant treated with isolate H that positively affect carbohydrate biosynthesis and photosynthesis, more specifically light-dependent protein. This data represents the major finding of this work, where root colonization rates were positively correlated with the global efficiency of the photosynthetic apparatus.

Therefore, the analysis of extracellular proteins and their role in mycorrhizal symbiosis still represents an active research field. A different approach to analyzed fungal secretome was applied by Pellegrin *et al.* (2015), where a broad set of fungi, including eleven ECM species among the forty-nine analyzed species. In detail, forty-nine Basidiomycota, six Ascomycota, one Zygomycota, and one Chytridiomycota were tested to determine if differences may be occurred in the secretome of ECM, saprotrophic and pathogenic fungi, mainly regarding SSPs protein abundance. Using the genomic sequences currently available on JGI (Joint Genome Institute), the authors set a specific bioinformatics pipeline to identify and localize the secretome composition of each species. Results showed as the number of predicted proteins did not change on the base of their lifestyle. However, ECM species showed an SSPs enrichment if compared with the other fungal species characterized by a different lifestyle. The presence of an enriched secretome in ECM fungi could be possibly explained through the conservation of SSPs from saprotrophic ancestors, and the expansion of symbiosis-specific SSPs dedicated to the molecular crosstalk between partners, the accommodation of hyphae in plant or the establishment and functioning of the symbiosis (Garcia *et al.*, 2015).

The 2-DE and mass spectrometry approach was also used to analyze the effect of the inoculation of *Lactarius isnuslus* in *Pinus massoniana* plants (Xu and Wu, 2016). *L. insulus*, also known as *L. zonarius*, is a pine ectomycorrhiza belonging to the family of Russulaceae representing one of the most studied pine ECM in china that was inoculated in *P. massoniana* seedlings and analyzed in drought stress conditions. Mycorrhized and non-mycorrhized plants were then compared, and results showed as abiotic stress affect the fungal proteome through the regulation of 22 protein spots. MS analysis leads to the identification of differentially expressed proteins, including a 1,4-benzoquinone reductase, an enzyme that prevents lignin degradation. According to the authors, this enzyme decreases in stress conditions as a possible response to drought stress, thus enhancing, as well as the other identified proteins, the drought resistance of *P. massoniana*.

Proteomic analysis was also employed for the study of arbuscular mycorrhizal (AM) symbiosis. Starting from the work of Dumas *et al.* (1990), a native PAGE gel-based approach was applied to detect qualitative protein modifications occurring during AM symbiosis establishment, and proteomics was used to disclose the key players involved in the plant–fungus association establishment.

The dissection of the root colonization process by AM fungi has led to the identification of four main phases (Bonfante and Genre, 2010): during an early stage, the communication between plant and fungus occurs: plant roots exude strigolactones and induce hyphal branching, while the fungus releases LCOs, perceived by the plant, where they trigger calcium spiking through the activation of the common SYM pathway; in the second stage, after that signal transduction has lead to the activation of cellular and transcriptional responses, the AM fungus contacts the root surface and forms hyphopodia; the contact with the root triggers the assembly of a broad but transient aggregation of cytoplasm, named the PrePenetration Apparatus (PPA) in the contacted epidermal cell and underlying outer cortical cell, that defines the path followed by the fungal hyphae toward the inner root layers; in the last stage, the fungal hypha branches and follows the path created by the PPA until the root cortex, where it starts to form a tree-like structure called ‘arbuscule’, which is the core of a functional AM symbiosis. The contact surface between the plant and the AM fungus greatly increases around the arbuscule, increasing the area where the exchanges of nutrients occur.

Proteomic studies have focused on the intracellular accommodation of unbranched hyphae (during the early stage) and arbuscules (at a later stage) to disentangle this coordinated developmental process between the plant and the fungal cells. The early stage of the interaction is essential to understand the crosstalk between the association actors and how the proteomes of the two organisms rearrange during the colonization events. Pioneering studies focused on the identification of fungal proteins involved in the early stages of the plant-fungus interaction: the identification of fungal proteins is more challenging, in respect proteomic of plant proteins, due to the impossibility to grow AM fungi in axenic cultures, to the lower amount of fungal biomass and to the more scanty sequence information. The first report of arbuscular mycorrhizal fungal protein identifications by using a proteomic approach is ascribable to Dumas-Gaudot *et al.* (2004): they used root-inducing transferred-DNA transformed roots of *Daucus carota* L., in vitro inoculated with *Glomus intraradices* (current name *Rhizophagus irregularis*), to enrich for proteins expressed in the extra-radical mycelium of the fungus. After producing the first 2DE reference map for the extra-radical proteome of an AM fungus with 438 spots, they were able to identify by mass spectrometry four protein: NmrA-like protein, an oxidoreductase, a heat-shock protein, and an ATP synthase beta mitochondrial precursor. The same experiment was repeated five years later by the same group (Recorbet *et al.*, 2009) but using a shotgun proteomic approach named GeLC-MS/M, and they were able to identify 92 different fungal proteins. GeLC-MS/MS method combines a mono-dimensional gel (1D-PAGE) and a nano-scale capillary liquid chromatography-MS/MS. Using the MetaCyc collection of more than a thousand metabolic pathways as reference (Caspi and Karp, 2007), the authors grouped those proteins in 11 pathways, comprising energy, metabolism, and cell rescue processes. Together with previous identifications of putative homologs of the cell-cycle gene in *Glomus mosseae* (current name *Funneliformis mosseae*) and *G. intraradices* (Jun *et al.*, 2002; Requena *et al.*, 2000), these results suggest that signaling pathways described in model species may also operate in AM fungi. Another milestone study on the early stage of root colonization is the one by Amiour *et al.* (2006), aimed at investigating the modifications of the *Medicago truncatula* root proteome elicited in response to appressorium formation by *G. intraradices*. In this study, using two-dimensional electrophoresis, the authors compared the root proteome from non-inoculated roots and from roots synchronized for appressorium formation. This approach was conducted in wild-type (J5), mycorrhiza-defective (TRV25, *dmi3*), and autoregulation-defective (TR122, *sun1*) *M. truncatula* genotypes. The work showed that proteins responding to appressorium formation were differentially expressed in different genotypes: the accumulation of proteins related to plant defense reactions, cytoskeleton rearrangements, and auxin signaling upon symbiont contact was recorded between wild-type and hypermycorrhizal genotypes.

In nature, the plant-fungus association is a very dynamic and complex event because, while arbuscules are forming and/or collapsing, new penetration events occur. Due to this, the proteomic analysis of the late stage of the AM symbiosis has never been an easy task; therefore, many studies on the late stage of the symbiosis focused their attention on a specific sub-cellular compartment on the effect of the established symbiosis on the proteome of the partners.

The first mass spectrometry (MS)-based identification of mycorrhiza-related proteins was reported by Bestel-Corre *et al.* (2002). In their work, a time-course analysis of root protein profiles was performed in the model plant *M. truncatula*, inoculated with the fungus *G. mosseae* or with the nitrogen-fixing bacterium *Sinorhizobium meliloti*. The proteins were separated by 2DE-PAGE and image analyses, followed by spots volume quantification to identify differentially expressed protein spots. Those spots were then excised from the gels and analyzed by mass spectrometry. In mycorrhizal roots, analyzed proteins included proteins related to defense responses, root physiology and respiratory pathway, e.g., a glutathione-S-transferase, a fucosidase, a myosin-like protein, a serine hydroxymethyltransferase and a cytochrome-c-oxidase.

In mycorrhizal symbioses, membrane proteins are essential because they likely include the receptors that control the plant-fungus crosstalk and the transporters that facilitate nutrients exchange. For these reasons, many papers have focused on membrane proteins using enrichment protocols.

Benabdellah *et al.* (1998) conducted the first study on the sub-cellular enrichment of membrane proteins. They analyzed the effect of AM colonization on tomato gene expression by comparing 2D-PAGE patterns of crude extracts, soluble and membrane proteins of tomato roots, either mycorrhizal with *G. mosseae* (Nicol. & Gerd.) Gerd. & Trappe or non-mycorrhizal, finding that 44 polypeptides were differentially displayed. In 2000, the same group identified for the first time a protein related to mycorrhizal symbiosis by Edman N-terminal sequencing, after plasma membrane enrichment and 2DE-PAGE protein separation (Benabdellah *et al.*, 2000). In 2005, Valot *et al.* (2005) also used a sub-cellular proteomic approach to record membrane-associated protein modifications during the plant-fungus interaction. Membrane proteins were extracted from *M. truncatula* roots either inoculated or not with the AM fungus *G. intraradices*. Comparative 2DE-PAGE revealed that 36 spots were differentially displayed in response to the mycorrhizal colonization, including 15 proteins induced, 3 up-regulated, and 18 down-regulated. 25 out of 36 regulated proteins were then identified using the MALDI-TOF, and none of them resulted in having been previously reported as being regulated during AM symbiosis. To investigate whether AM symbiosis-specific proteins accumulate when the plant plasma membrane (PM) invaginates around the fungal arbuscular structures resulting in the periarbuscular membrane formation, two complementary MS approaches targeting the root PM from *M. truncatula* were used by the same group a year later (Valot *et al.*, 2006). They enriched samples for PM using a discontinuous sucrose gradient method, and the resulting fractions were analyzed with two complementary proteomics methodologies: (1) an automated 2D liquid chromatography-tandem mass chromatography (LC-MS/MS) using a strong cation exchange and reverse phase chromatography, and (2) SDS-PAGE combined with a systematic LC-MS/MS analysis. Only proteins consistently retrieved with the two methodologies were taken into account, resulting in the identification of 78 proteins: of those, 56% were predicted to contain one or more transmembrane domains, while 30% were already known to be localized on the plasma membrane. Comparison between non-inoculated and *G. intraradices*-inoculated roots revealed two proteins that differed in the mycorrhizal root PM fraction: a proton-efflux P-type ATPase (Mtha1) and a predicted glycosylphosphatidylinositol-anchored blue copper-binding protein (MtBcp1). The correct localization of MtBcp1 in the plasma membrane and the periarbuscular membrane around the arbuscular trunk was confirmed a few years later by Pumplin and Harrison (2009), while Wang *et al.* (2014) showed that H⁺-ATPases are required for enhanced proton pumping activity in membrane vesicles. Recently, Aloui *et al.* (2018) performed a comparative protein profiling of PM fractions from *M. truncatula* roots either inoculated or not with the *Rhizophagus irregularis* to obtain a global overview at the proteome level of the host PM proteins as modified by the symbiosis. The analysis of PM proteins isolated from root microsomes using an optimized discontinuous sucrose gradient, by liquid chromatography followed by mass spectrometry, identified 674 proteins. In their work, the analytic downstream workflow allowed for identifying a set of 82 mycorrhiza-responsive proteins that provided insights into the plant PM response to mycorrhizal symbiosis. The PM-associated proteins responsive to mycorrhization also supported host plant control of sugar uptake to limit fungal colonization and lipid turnover events in the PM fraction of symbiotic roots.

Gaude *et al.* (2012), investigating cell type-specific proteome changes in arbuscule-containing cells, provided a solid evidence that the PM acts as important carbon sink in the mycorrhizal symbiosis. They combined Laser Capture Microdissection and LC-MS/MS to determine the specific protein composition in arbuscule-containing cortical cells (arb) and cortical cells of non-mycorrhizal *M. truncatula* roots (cor). From both cell types, they identified 401 *M. truncatula* proteins with similarities to annotated proteins: 188 were exclusively detected in arb cells, whereas 53 proteins were exclusively found in cor cells. The proteome of arb cells showed a strongly increased number of proteins involved in lipid metabolism, most likely related to the synthesis of the PM, such as a ACC-carboxylase, a biotin carboxylase and a β -ketoacyl synthase, while transcriptome data of cor cells suggest mobilization of carbon resources and their symplastic transport toward arbuscule-containing cells for the synthesis of PMs.

Investigating the membrane proteome of *M. truncatula* roots in response to arbuscular mycorrhizal symbiosis with *R. irregularis*, Abdallah *et al.* (2014) were able to identify 1226 root membrane proteins and to report for the first time the proteomic identification of previously functionally characterized symbiosis marker genes (MtPt4, GmAMT4.1, STR half-ABC transporters and VAMP721d/e). In this work, the sample pre-fractionation was performed using 1D SDS-PAGE, and the proteins were quantified by label-free counting: peptide peak intensity and spectral count were measured for individual LC-MS/MS or LC/LC-MS/MS runs, and changes in protein abundance were calculated via a direct comparison between different analyses. With this approach, the authors were able to speculate that accommodation of AM fungi within cortical root cells implies both a dynamic reorganization of the root membrane proteome and the de novo synthesis of AM-related proteins. The effects of arbuscular mycorrhizal symbiosis have also been explored in other plant tissues. Peinado-Guevara *et al.* (2017) performed a comparative proteomic study to analyze the differential accumulation of leaf proteins in response to the symbiosis between *Solanum lycopersicum* and the *R. irregularis*. 2D-SDS-PAGE revealed that 27 spots were differentially accumulated in tomato plants colonized with AMF (M) vs. non-colonized plants fertilized with low phosphate (NM-LP), 23 of which were successfully identified by mass spectrometry. Two of these proteins, 2-methylene-furan-3-one reductase, and auxin-binding protein ABP19a, were up-regulated in M plants. Superoxide dismutase, harpin binding protein, and thioredoxin peroxidase were also down-accumulated in leaves of M tomato plants when compared to NM-LP and to non-colonized plants fertilized with regular phosphate Hoagland's solution, indicating that these proteins are responsive to AMF colonization independently of the phosphate regime under which they were grown.

AM mycorrhizal symbioses have also been investigated for changes in their protein profiles when exposed to abiotic or biotic stresses. Mycorrhizal symbioses contribute to plant growth and plant protection against various environmental stresses or combination of stresses that include drought, salinity, temperature, nutrients, and heavy metals (Begum *et al.*, 2019; Lenoir *et al.*, 2016). Many studies

have been carried out to demonstrate the benefits of the mycorrhizal plant–fungus interaction against environmental stresses. The proteomic approach has been employed to identify the key proteins potentially involved in mycorrhiza-mediated stress tolerance. One of the most investigated protective features of mycorrhizal symbioses is the capability to reduce heavy metal toxicity to the host in soils with potentially toxic amounts of soluble and insoluble metals. [Aloui et al. \(2009\)](#) report on the protective effect conferred by AM symbiosis to *M. truncatula* grown in the presence of Cd; they further used a 2-D-based proteomic approach, followed by MS/MS, to compare the proteomes of *M. truncatula* roots either colonized or not with *G. intraradices* in Cd-free and Cd-contaminated substrates. They identified six mycorrhiza-related proteins that displayed changes in abundance upon Cd exposure: a cyclophilin, a guanine nucleotide-binding protein, a ubiquitin carboxyl-terminal hydrolase, a thiazole biosynthetic enzyme, an annexin, a glutathione S-transferase (GST)-like protein, and an S-adenosylmethionine (SAM) synthase. These results suggested that part of the symbiotic program, which displays low sensitivity to Cd, might be recruited to counteract Cd toxicity through the mycorrhiza-dependent synthesis of proteins having functions putatively involved in alleviating oxidative damages, including. [Bona et al. \(2010\)](#) studied the leaf proteome of the arsenic hyperaccumulator fern *Pteris vittata* inoculated with *G. mosseae* and *Gigaspora margarita*, with and without arsenic treatment. The downregulation of oxidative damage-related proteins indicated a protective role for AM fungi colonization in the absence of arsenic. The up-regulation of multiple forms of glyceraldehyde-3-phosphate dehydrogenase, phosphoglycerate kinase, and enolase, mostly in *G. mosseae*-inoculated plants, suggests a central role for glycolytic enzymes in arsenic metabolism. [Cangahuala-Inocente et al. \(2011\)](#) analyzed the root proteome of grapevine rootstock Selection Oppenheim 4 (SO4) upon colonization with two AMF, *Glomus irregulare* (current name *Rhizophagus irregularis*), and *G. mosseae*. At the proteome level, changes in protein amounts due to AMF colonization resulted in 39 differentially accumulated 2D-PAGE spots in AMF roots relative to control. Out of them, 25 were co-identified in SO4 roots upon AMF colonization, supporting the existence of conserved plant responses to AM symbiosis in a woody perennial species.

In a long time-course experiment, [Lingua et al. \(2012\)](#) demonstrated the success of phytoremediation by mycorrhizal poplars, as both copper and zinc concentrations in soil were significantly reduced. In this work, leaf samples of a clone of *Populus alba* L., previously selected for its tolerance to copper and zinc and pre-inoculated or not with *G. intraradices*, were collected from plants maintained in a glasshouse on polluted (copper and zinc contaminated) or unpolluted soil, after four, six and sixteen months of growth. At each time point, about 450 proteins were constantly separated on 2-DE maps, and protein identification was performed by nanoLC Coupled with Q-TOF MS/MS. At the first harvest, the most relevant effect on protein modulation was exerted by the AM fungi, at the second one by the metals, and at the last one by both treatments. In a similar experiment, [Guarino et al. \(2014\)](#) demonstrated the effectiveness of the application of an AMs/PGPRs cocktail in promoting growth (both in terms of stem diameter and height values) and ameliorating metal toxicity in *Eucalyptus camaldulensis* plants, even if they are grown on a contaminated site. Using 2-DE coupled with nanoLC-ESI-LIT-MS/MS equipped with an LTQ XL mass spectrometer, they showed how the addition of AMs/PGPRs mixture to the soil increased the activation of enzymes involved in photosynthesis and the Calvin cycle, suggesting the existence of signaling mechanisms that address the energy/reductive power requirement associated with augmented growth performances. Moreover, since proteins guaranteeing elevated glutathione levels were constantly over-represented in the presence of AMs/PGPRs or in plants exposed to HMs for prolonged periods, the Authors suggested that glutathione (and related phytochelators) could act as key molecules for ensuring the effective formation of HMs-chelating complexes, which are responsible for the observed plant tolerance to metal stresses. More recently, by means of the Isobaric Tag for Relative and Absolute Quantification (iTRAQ) system, [Wu et al. \(2020\)](#) evaluated differentially expressed proteins (DEPs) in *Phragmites australis* under metal-stressed conditions and inoculated with *R. irregularis*. They reported that under copper stress, which not only reduces plant biomass but also inhibits photosynthesis, the inoculation of *R. irregularis* induces a total of 459 differently expressed proteins (200 up-regulated and 259 down-regulated) in root buds. The photosynthetic changes triggered by AMF inoculation mainly involve the up-regulated expression of transmembrane protein–pigment complexes CP43 (photosystem II) and FNR (ferredoxin-NADP + oxidoreductase related to photosynthetic electron transport). Salt stress is one of the most important abiotic stresses and limiting factors for plant growth and agricultural production. The mechanism of salinity stress alleviation by AM fungi has also been investigated with proteomic approaches. [Jia et al. \(2019\)](#) studied how the inoculum of *R. irregularis* could alleviate NaCl salinity stress in *Elaeagnus angustifolia*. The experimental design comprised four different treatments: *E. angustifolia* inoculated with *R. irregularis* without salt stress; *E. angustifolia* inoculated with *R. irregularis* under salt stress (300 mmol/L NaCl), *E. angustifolia* non-inoculated without salt stress, and *E. angustifolia* non-inoculated under salt stress (300 mmol/L NaCl). The proteomic analyses indicated that inoculated *E. angustifolia* seedlings increased the secondary metabolism level of phenylpropane metabolism, enhanced the signal transduction of Ca^{2+} and ROS scavenging ability, promoted the biosynthesis of protein, accelerated the protein folding, and inhibited the degradation of protein under salt stress. The study by [Wang et al. \(2019\)](#) was also aimed to provide new insights into the positive role of AMF in the alkali tolerance of *Puccinellia tenuiflora* and clarify how AMF colonization could affect the physiological adaptation strategies and molecular regulation network of this species in alkali-degraded soil. iTRAQ were used to identify the differentially abundant proteins in plant seedlings inoculated or not inoculated with *Rhizophagus intraradices*, under alkalinity stresses (0, 100, 200, and 300 mM of NaHCO_3). The Authors reported that a total of 598 proteins were significantly differentially regulated in *P. tenuiflora* seedlings after AMF inoculation under alkalinity stress compared with under alkalinity stress alone. Moreover, *R. intraradices* inoculation significantly improved protein synthesis, reactive oxygen species scavenging, and nitrogen metabolism to promote the biosynthesis of osmotic substances in response to alkalinity stress. Drought is another constraint that plants must face in some areas of the world, hugely aggravated by climate changes, which are recognized to affect the worldwide plant productivity negatively. AMF inoculations, with their bio-fertilization features, may represent a natural and sustainable way to reduce the negative effects due to drought in the crop, enhancing plant growth and development. [Bernardo et al. \(2017\)](#) have

investigated the modulation of wheat root proteome induced by *G. mosseae* inoculation under drought stress, using bread and durum wheat cultivar. Proteomic analyses were performed with SDS-PAGE followed by a shotgun tandem MS approach, using nanoscale liquid chromatography coupled to a hybrid quadrupole-time-of-flight (Q-TOF) mass spectrometer. The Authors identified 50 statistically differential proteins in the bread wheat cultivar and 66 differential proteins in the durum wheat cultivar. The results showed a regulation of proteins involved in sugar metabolism, cell wall rearrangement, cytoskeletal organization, and plant stress responses. Both cultivars showed a down regulation of the sucrose: fructan 6-fructosyltransferase, but a specific response upon AMF interaction was evidenced in durum wheat: two proteins related to the biosynthesis of jasmonic acid (12-oxo-phytodienoic acid reductase and a jasmonate-induced protein) was found to be regulated. These results indicate that the AMF association helps wheat roots reducing the osmotic stress and maintaining cellular integrity. Olalde-Portugal *et al.* (2020) used a consortium formed by *Septoglomus constrictum*, *Funneliformis geosporum*, *Rhizophagus fasciculatum*, *Glomus tortuosum* (current name *Sieverdingia tortuosa*), *G. margarita* and *Acaulospora scrobiculata* to inoculate plants of *Sorghum bicolor* L. Moench (a drought-tolerant crop model) in order to understand the water deficit stress mechanism in colonized and non-colonized plants. 2-DE profiles revealed 51 differentially regulated proteins in response to water deficit, 49 of which were successfully identified by HPLC/MS. They found that, in mycorrhizal plants, proteins related to energy metabolism (ATP synthase-24 kDa, ATP synthase β), carbon metabolism (malate dehydrogenase, triosephosphate isomerase, sucrose-phosphatase), oxidative phosphorylation (mitochondrial-processing peptidase), and sulfur metabolism (thiosulfate/3-mercaptopyruvate sulfurtransferase) were found to be regulated and putatively involved in protection against water deficit. A further confirmation that AM fungi can substantially contribute to plant drought tolerance comes from the Gui *et al.* (2020). They used an iTRAQ-based proteomics approach to evaluate the inoculation effects of *Funneliformis mosseae* on blueberry (*Vaccinium corymbosum*) 'O'Neal' cultivated under well-watered or drought-stressed conditions. The proteomic analysis identified 501 differentially abundant proteins (DAPs), including 127, 30, 236, and 108 DAPs in drought-stressed plants vs. well-watered, drought-stressed plants with AMF inoculation vs. well-watered plants with AMF inoculation, AMF-inoculated well-watered plants vs. non-inoculated well-watered plants, and AMF-inoculated plants under drought stress vs. non-inoculated plants under drought stress paired comparisons, respectively. Specifically, AMF-inoculated plants drought-stressed showed a greater abundance of DAPs involved in amino acid metabolism, antioxidant system, signal transduction, and photosynthesis, including carbon fixation in photosynthetic organisms, porphyrin and chlorophyll metabolism, and carotenoid biosynthesis.

As highlighted, AM fungi promote plant growth and alleviate various stresses, but it remained poorly unexplained how the AMF influence resistance against the pathogen. Turetschek *et al.* (2017) analyzed the infection response of two *Pisum sativum* cultivars with varying resistance levels towards *Didymella pinodes* comprehensively at proteomic and metabolomic levels. Proteomic analyses were performed by means of GC-MS and nanoESI LC-MS/MS. The results showed that symbionts (*G. mosseae* and *Rhizobium leguminosarum* bv. *viciae*) induced variation of the host's infection response, which, however, was overruled by genotypic resistance-associated traits of the tolerant cultivar such as maintenance of photosynthesis and provision of sugars and carbon backbones to fuel secondary metabolism. The Authors remark that resistance appears to be linked to sulfur metabolism, a functional glutathione-ascorbate hub, and fine adjustment of jasmonate and ethylene synthesis, essential traits for sustenance of cell vitality and thus, a more efficient infection response. In addition, Sistani *et al.* (2020) focused on the protective effects of a commercial mycorrhizal inoculum (containing *Claroideoglomus etunicatum*, *C. claroideum*, *R. irregularis*, *F. geosporus*, and *F. mosseae*) against *D. pinodes* on two different *P. sativum* cultivars. Regarding the soybean (*Glycine max*), this plant is susceptible to root rot when subjected to continuous cropping, and this disease can seriously diminish the crop yield. The primary root rot agents include several *Fusarium* species, *Rhizoctonia solani*, *Phytophthora* sp., as well as other fungi. Bai *et al.* (2019) used iTRAQ labeling and liquid chromatography-tandem mass spectrometry (LC-MS/MS) to perform proteomic analysis of continuously cropped soybean inoculated with the AM fungus *F. mosseae*. They showed that the AMF inoculum could reduce the incidence of root rot and increase plant height, biomass index in 1, 2, and 4 years of continuous cropping. At the 1-year time point, 131 DEPs were identified in *F. mosseae*-treated samples, of which 49 and 82 were up- and down-regulated, respectively. The up-regulated levels of glucan 1,3beta-glucosidase, chalcone isomerase, calcium-dependent phospholipid binding, and other defense-related proteins triggered by *F. mosseae*, suggested that inoculation promotes the growth and development of soybean and increases disease resistance.

More recently, proteomic analyses have been used in support of and to validate findings obtained by High Throughput Sequencing technologies and to complement genomic studies. For example, when testing the hypothesis that tomato plants grown on native soils may exert different responses to soil microbiotas, Chialva *et al.* (2018) used transcriptomics, proteomics, and direct quantification of biochemical compounds to describe the responses of two tomato genotypes (susceptible or resistant to *Fusarium oxysporum* f. sp. *lycopersici*), grown on an artificial substrate and two native soils conducive and suppressive to *Fusarium*. In order to study the plant transcriptome under the native soils and the control substrate conditions, the root transcriptome of the 'Battito' (resistant) and 'Cuore di Bue' (susceptible) genotypes were sequenced by RNA-seq. To complement the transcriptomic data, proteome profiling was performed by LC-MS/MS on the same material used for RNA-seq but limited to the 'Cuore di Bue' genotype. The researchers found out that the molecular profile of the tomato roots grown in native soils was different from those grown on control substrate, since the native soil modulate pathways involved in responses to oxidative stress, phenol biosynthesis, lignin deposition, and innate immunity, particularly in the suppressive soil. In tomato plants grown on steam-disinfected soils, total phenols and lignin decreased significantly. This led to the conclusion that the tomatoes grown on native soils built up fortified walls and were already trained to use defensive strategies present in their genome.

Moreover, they showed that the wary response of tomato plants could be, in large part, triggered by *F. mosseae* inoculation to the disinfected soils. Murphy *et al.* (2020) examined the extraradical mycelium proteomic profile of *R. irregularis* grown on Ri

T-DNA transformed Chicory roots in a root organ culture setting. With SDS-PAGE and LC-MS/MS analysis, they detected 529 different peptides that mapped to 474 translated proteins in the *R. irregularis* genome. In particular, they found a high proportion of proteins mediating several signal transduction processes, e.g., Rho1 and Bmh2, Ca-signaling (calmodulin, and Ca channel protein), mTOR signaling (MAP3K7, and MAPKAP1), and phosphatidate signaling (phospholipase D1/2) proteins, as well as members of the Ras signaling pathway. Forty-eight proteins were predicted to be associated with surface/membrane, including multiple hypothetical proteins of unknown functions. Finally, they were able to identify a core set of pathways and processes involved in AMF growth comparing the of *R. irregularis* proteome to previously published AMF proteomes.

Finally, it is worth mentioning that endobacteria have been observed to inhabit some mycorrhizal and pathogenic fungi (Bonfante and Anca, 2009). For example, a nitrogen-fixing bacterium was detected inside the pathogenic fungus *Ustilago* (Ruiz-Herrera *et al.*, 2015), the genome of a beta proteobacterium living inside *Mortierella* (Fujimura *et al.*, 2014), and the genomes of Mollicutes-related endobacteria living inside many arbuscular mycorrhizal fungi have been sequenced (Naito *et al.*, 2015; Torres-Cortés *et al.*, 2015). The AM fungus *G. margarita* hosts an obligate, stable and structurally integrated population of the gram-negative bacterial endosymbiont *Candidatus Glomeribacter gigasporarum* (*Ca. G. gigasporarum*; Bianciotto *et al.*, 2003; Jargeat *et al.*, 2004). The sequencing of this endobacterium revealed genome traits indicating the strict metabolic dependency on the fungal host for nutrients and energy, explaining why the bacterium cannot be cultured outside its host (Ghignone *et al.*, 2012). A *G. margarita* line lacking its endobacteria (named as B- or cured line) was developed and derives from a stable wild-type (named as B+ or wt line) variant that is still able to establish mycorrhizal symbiosis (Lumini *et al.*, 2007). To shed light on the bacterial effect on fungal fitness, Salvioli *et al.* (2016) used NGS to analyze the transcriptional profile of *G. margarita* in the presence and absence of its endobacterium. To complement this previous study, Vannini *et al.* (2016) employed the iTRAQ approach to analyze the proteomic profile of *G. margarita* and its endobacterium and to improve the coverage of the protein changes associated with endosymbiosis. While RNA-seq analysis of the fungus in the presence and absence of the endobacterium indicated that endobacteria have an important role in the fungal pre-symbiotic phase by enhancing fungal bioenergetic capacity, this proteomic study revealed that endobacteria influenced fungal growth, calcium signaling, and metabolism, with a significant role on fungal primary metabolism and respiration.

Proteomics of Plant Pathogens Fungi

The study of the plant-pathogen interactions has been efforted in the last years by large scale analysis as the proteomics. The development of new mass spectrometry-based methods has significantly increased the possibility of going further in the analysis of the host-pathogen interaction by deciphering most of the aspects related to fungal infection. Pathogenic fungi are classified based on parasitism and infection strategies and consists of three groups: biotrophic (e.g., *Ustilago maydis*) and hemibiotrophic (e.g., *Magnaporthe oryzae*), that requires living plant tissues to survive and complete the life cycle (Koeck *et al.*, 2011), and necrotrophic. This latter group includes fungi (e.g., *Botrytis cinerea*) that kill the host by producing cell wall-degrading enzymes and phytotoxins, aiming to get nutrients for growth and reproduction (Hakeem *et al.*, 2016).

The complicated life cycle of fungal pathogens consists of sexual and asexual reproduction, together with life stages involving the formation of different infective, vegetative, and reproductive structures (Glawe, 2008). The studies of fungal pathogen strategy for plant colonization have performed using a wide range of approaches, including biochemistry and high-throughput -omics techniques (González-Fernández *et al.*, 2010), including proteomics.

The proteomic approach to plant pathogenic fungi was firstly applied in two pioneering works, both related to *Cladosporium fulvum* inoculated on tomato leaves. In the first work (De Wit *et al.*, 1986), a gel-based approach of intercellular fluid analysis was coupled with radioimmunological detection to firstly report the avirulence protein Avr9, whereas, in the second work, the purification and characterization of the putative peptide elicitor of Avr9 was performed by PAGE separation, reverse phase HPLC purification and sequencing using a gas-phase protein sequencer (Schottens-Toma and de Wit, 1988).

Starting from these works, proteomic analyses were applied to a wide range of plant pathogenic fungi, also thanks to recent advances in modern technology, and most of the papers are mainly focused on species that cause a severe loss of production. This group includes species such as *B. cinerea*, *Sclerotinia sclerotiorum*, *Fusarium graminearum* and *M. oryzae* that are considered as some of the most harmful species for crop production (Dean *et al.*, 2012).

Botrytis cinerea

The fungal pathogen *B. cinerea* causes severe loss in crop production on over 200 dicotyledonous crop species. This species is difficult to control because It attacks plants in different ways, uses the different hosts as inoculum source, and can also survive through sclerotia production in crop debris (Williamson *et al.*, 2007).

The first proteomic study about *B. cinerea* was published by Fernández-Acero *et al.* (2006), where 22 protein out of selected 64 spots were identified through a 2-DE approach coupled with MS analysis (MALDI-TOF/TOF and ESI ion trap) using mycelium. The identification of proteins showed that many of them can be ascribed to primary metabolism (malate dehydrogenase, MDH, and glyceraldehyde-3-phosphate dehydrogenase, GADPH) or strain virulence (e.g., cyclophilin). Following this first paper, the same research group published a second chapter aiming to identify proteins involved in virulence (Fernández-Acero *et al.*, 2007). Comparative analyses were carried out using two mycelium strains, which differ in virulence. The 2-DE analysis allows identifying 73 differentially regulated spots, among which only 27 results in protein identification. These proteins were belonging to similar

metabolism as the previous work, but resulting as upregulated in virulent strain, thus suggesting their possible role as pathogenicity factors. These achieved were performed through a third work (Fernández-Acero *et al.*, 2009), where the fungal proteome map was defined under cellulose degradation to define the fungal proteome map during cellulose degradation. This result was achieved by adding carboxymethylcellulose to the growth media of three mycelial cultures.

By using a gel-based approach (2-DE and MALDI TOF/TOF) as before, 303 proteins were identified out of 267 selected spots. Proteins were then functionally classified, and authors mentioned as most of them are involved in the pathogenicity process and, therefore, possible targets of antifungal activity. The same group also published a review on the new potential use of the proteomic approach for the development of proteomics-based fungicides (Fernández Acero *et al.*, 2011). Furthermore, the phosphoproteome of *B. cinerea* was also analyzed to detect changes induced by two different carbon sources used as plant-based elicitors; glucose and deproteinized tomato cell wall (TCW) (Liñeiro *et al.*, 2016). Using a gel-free approach (LC-MS/MS, Orbitrap Velos Pro), 173 and 11 phosphoproteins were identified exclusively in the presence of glucose and TCW, respectively. Gene ontology (GO) analysis reported that most of the unique proteins belong to signaling and transmembrane transport, thus reinforcing the hypothesis that these processes are essential in fungal adaptation to environmental changes. Results were then expanded by analysis of membrane phosphorylated proteins, going more in-depth in the so-called “phosphomembranome” analysis (Escobar-Niño *et al.*, 2019). Using different carbon sources, glucose as constitutive stage and tomato cell wall (TCW) as virulence inductor, authors applied a gel-free approach (LC-MS/MS) that allowed define a specific subproteome pattern, were differentially expressed proteins belongs to several metabolisms (e.g., pyruvate metabolism, unfolded protein response, cell death, thus).

The study of *B. cinerea* proteome was also extended to its secretome, which was analyzed in several works under different experimental conditions (Shah *et al.*, 2009a,b; Fernández-Acero *et al.*, 2010; Espino *et al.*, 2010). In the first paper, Shah *et al.* (2009a) used a gel-based approach (1-DE and LC-MS/MS) to detect differences in secreted proteins as a response to the use of mock infecting media supplemented with tomato, strawberry, and Arabidopsis leaf extracts. MS analysis identified 89 proteins among all the analyzed growth conditions, among which transport proteins, peptidases, and pathogenicity factors were identified, providing new insight about the use of *B. cinerea* secreted proteins for plant infection and colonization.

Following the first work, Shah *et al.* in 2009 published a second paper (Shah *et al.*, 2009b) still dealing with the interaction between host and pathogen by analyzing the impact of the degree of esterification of pectin on the fungal secretion. By using three different carbon nutrient sources, authors analyzed changes occurring during fruit ripening and then describing their role as triggers in the activation of *B. cinerea* from the dormant state to an active infection.

The secretion of *B. cinerea* proteins was also analyzed in the third work (Fernández-Acero *et al.*, 2010), where different carbon sources and plant elicitors (glucose, cellulose, starch, pectin, and tomato cell walls, TCW) were used to induced protein production. The analysis of 2-DE profiles indicates that the number of resolved spots increased when specific elicitors (cellulose and TCW) were added to growth media. Mass spectrometry (MALDI-TOF/TOF) analyses have led to the identification of 95 proteins (56 unique) out of 76 selected spots, some of which involved in the pathogenicity process (i.e., xylanases).

Modified growth media was also used in a fourth work (Espino *et al.*, 2010), where *B. cinerea* conidia were germinated in conditions that resembled the plant environment by adding low molecular weight plant compounds (tomato, strawberry, and kiwi-fruit) to analyze the early secretome. Secreted proteins were then collected after 16 h, and 2-DE-MALDI-TOF analyses identified 11 different proteins out of 16 differential expressed spots. These proteins were identified from a broader set of selected spots (86), so the authors did perform an alternative procedure for protein identification based on 1-DE coupled with LC-MS/MS, thus resulting in a higher number of identified proteins (105), mostly proteases able to degrade plant cell wall.

Secretome analysis was also performed on *B. cinerea* samples grown under different pH conditions (pH 4 and pH 6) to identify the role of ambient pH in protein secretion (Li *et al.*, 2012). Comparative analyses were performed using a gel-based approach to identify 21 unique proteins out of 47 differentially expressed spots. Among these proteins, authors indicate an upregulation of proteolysis proteins at pH 4, whereas the cell wall degrading enzymes were upregulated at pH 6. Proteomic data were then coupled with gene expression analysis (qPCR), confirming as expressions of differential proteins were mainly regulated at the transcription level (Li *et al.*, 2012). Further works were then published about *B. cinerea* secretome, by comparing the secretome of different strains (González-Fernández *et al.*, 2014), deepening the secretome composition through in vitro study (González-Fernández *et al.*, 2015), and identifying specific proteins that occurred during virulence pathogenicity process (Brito *et al.*, 2006; González *et al.*, 2014) or in plant defense response (Frías *et al.*, 2011; Frías *et al.*, 2016).

Sclerotinia sclerotiorum

S. sclerotiorum is a necrotrophic fungus that infects over 400 plant species worldwide, including much important crop species (Bolton *et al.*, 2006). The first comprehensive proteomic study of the *S. sclerotiorum* mycelia and secretome was published in 2006 (Yajima and Kav, 2006), getting new information about the life cycle as well as its phytopathogen activity. Combining 2-DE and LC-MS/MS analysis, authors identified 18 secreted and 95 mycelial proteins, including pathogenicity or virulence factors, one of which (alpha-L-arabinofuranosidase) was never reported before. Further studies were focused on sclerotia formation (Liang *et al.*, 2010a), which are long-term multihyphal structures that can remain dormant until a favorable opportunity for germination and growth occurs (Willets and Bullock, 1992). These structures represent a primary inoculum source for many crop species, and their development was analyzed at three representative stages of sclerotia development through a gel base approach (2-DE and LC-MS/MS). Results indicated as 88 protein spots were identified as differentially abundant among the different experimental conditions. These proteins were then classified into functional categories (e.g., metabolism, energy, cell defense, melanogenesis), also indicating the presence of a development-specific protein (SSP), which may have an essential role in the formation and germination of sclerotia (Liang *et al.*, 2010a). Besides that, the

same research group did also applied a proteomic approach to elucidate the protein composition of liquid sclerotial exudates, which are commonly produced during sclerotia formation (Liang *et al.*, 2010b). Fifty-six proteins were identified and then grouped in different functional categories (e.g., amino acid metabolism, carbohydrate metabolism, lipid, and secondary metabolism), giving new insight about the biological role and the composition of these exudates. More recently, the cell wall proteome was analyzed to determine if its structure could be influenced by the presence (using a PDA growth media) or the absence (using a Vogel's glucose medium) of plant-derived signals (Liu and Free, 2016). A bottom-up approach based on gel separation (SDS-PAGE) and MS analysis was employed and results indicated as the hyphae grown in the presence of plant materials contain a number of additional proteins (laccases, oxalate decarboxylase), that might improve the fungal growth on a plant host. Moreover, some of these cell wall proteins (11) were identified as encoded explicitly by *Sclerotinia* and *Botrytis* genome. In 2020, the knowledge of *S. sclerotiorum* proteome was greatly improved by the recent release of the paper of Otun and Ntushelo (2020), where a gel-based approach (SDS-PAGE and AB Sciex TripleToF 6600-MS) was applied, leading to the identification of 1471 proteins. This paper represents the most comprehensive work on *S. sclerotiorum*, giving new information useful to elucidate the various physiological processes of *S. sclerotiorum*.

Fusarium graminearum

F. graminearum Schwabe [teleomorph *Gibberella zeae* (Schweinitz) Petch] is a fungal pathogen that is the causal agent of Fusarium head blight in several grain species (wheat, barley) that causes severe yield and quality losses. Besides, infected grains may contain high levels of trichothecenes mycotoxin (e.g., deoxynivalenol, DON) that inhibit eukaryotic protein biosynthesis causing severe diseases in human and animals (Goswami and Kistler, 2004; Trail, 2009; Yang *et al.*, 2013).

Considering these aspects, proteomic studies on *F. graminearum* have mainly focused on two aspects: secretome analysis and potential impact of mycotoxin production in the host infection process. The first published study on the secretome of this fungus was performed using a fungal culture grown in medium containing glucose or hop cell walls (*Humulus lupulus*, L.). Through a gel-based approach (1D-2D and LC-MS/MS), the authors identified 23 and 84 unique proteins, respectively, with a prevalence of cell degrading enzymes in the cell wall-grown secretome (Phalip *et al.*, 2005). Following this work, the *F. graminearum* secretome was also analyzed by ming the nutritional condition of fungus in the plant, by using wheat or barley flour as a unique nutrient source. The protein secreted in the culture medium was identified using a gel-based approach, resulting in 69 unique fungal proteins. Secretome composition quantitatively differing between different flour substrates, mainly in enzymes involved in the remodeling and degradation of plant cell walls (Yang *et al.*, 2012). Different approaches were also applied to deepening the knowledge of *F. graminearum* secretome. Using a high-throughput LC-MS/MS gel-free approach, 289 secreted proteins were identified using 13 different growth media (in vitro and planta), mostly glycoside hydrolases and proteases (Paper *et al.*, 2007). Secretome composition was also analyzed to describe the role of a subset of proteins that are required to initiate the infection, which removal results in reduced pathogenicity.

Using a label-free quantitative approach, the secretome of wild type and two non-pathogenic mutants of *F. graminearum* were analyzed. The results reveal a subset of 29 proteins differentially regulated proteins, as measured by spectral counting; some of these proteins decreased in abundance, thus representing potential candidates virulence factors (Rampitsch *et al.*, 2013).

The role of mycotoxin production was evaluated using specific fungal strain, where a gel-based approach (2D DIGE coupled with MALDI-TOF/TOF analysis) was applied on a nivalenol (NIV)-producing strain, leading to the identification of 1102 proteins, many of which never reported before (Pasquali *et al.*, 2013).

A gel-free approach based on iTRAQ analyses was employed to perform a complete protein profile of *F. graminearum* expression under mycotoxin-inducing conditions. Comparative proteomic analysis reveals 130 differentially regulated proteins, with an upregulation in those involved in virulence. In contrast, the cluster of downregulated proteins included enzymes involved in primary metabolism, protein chaperones, or proteins involved with the cellular translational machinery (Taylor *et al.*, 2008).

The proteome of *F. graminearum* was also assessed in response to viral infection (Kwon *et al.*, 2009), to identify changes triggered by the polyamine agmatine (Pasquali *et al.*, 2016) or to evaluate the polygalacturonase activity (Ortega *et al.*, 2014). In the first work, the *F. graminearum* virus-DK21 was used to infect *F. graminearum* strains. The analysis was carried out using a gel-based approach (2-DE-ESI-MS/MS), leading to 23 proteins out of 19 differentially regulated spots (Kwon *et al.*, 2009). Seven of these proteins resulting as upregulated, whereas the other sixteen, including enolase, saccharopine dehydrogenase, and flavohemoglobin resulted as downregulated. The second work analyzed the effect of an environmental stimulus at a proteomic level (Pasquali *et al.*, 2016). By adding the polyamine agmatine and glutamic acid as the sole nitrogen source, the production was induced in three different genetic chemotypes. A gel-based approach (2-D DIGE) highlights that proteomic profile and phenotype were drastically reshaped by agmatine, which modulated several proteins, including structural and virulence-related ones. The third work described the use of proteomic tools for purification and characterization of polygalacturonase enzyme, which is essential in the process of virulence. Using a gel-based approach (SDS-PAGE and MALDI TOF/TOF) on purified extracts from wheat spikes, the authors isolated and identified two proteins, including an endopolygalacturonase. This protein was then functionally characterized, in terms of optimum pH and temperature as well as metal ions sensitivity, giving new insight about the enzymatic mechanisms and role of polygalacturonase in the establishment of infection on wheat (Ortega *et al.*, 2014). Proteomic analyses in *F. graminearum* were also extended to phosphoproteomic to verify how phosphorylation events are involved in activating the trichothecene pathway under nitrogen-limiting conditions (Rampitsch *et al.*, 2010). The analyses were performed using different proteomic approaches (gel-free and gel-based), leading to the identification of 348 phosphorylation sites localized in 301 peptides from 241 proteins, including ten kinases and seven transcription factors. Following this first report, a second paper (Rampitsch *et al.*, 2012) was released where the phosphoproteome was analyzed without any nutritional limitation. In this case,

2902 putative phosphopeptides with homologous matches to 1496 different proteins were identified, mostly nuclear proteins with ATP-binding function.

Magnaporthe oryzae

M. oryzae is a filamentous ascomycete fungus that represents the causal agent of the most destructive rice disease worldwide, the rice blast disease (Ou, 1980; Dean *et al.*, 2012). Many papers employed the use of proteomic tools to describe the host-pathogen interaction from a plant point of view, which were gathered in a recently published review (Meng *et al.*, 2019). Despite this, some publications have covered the analysis of the fungus proteome, including the analysis of the fungal secretome (Wang *et al.*, 2011; Jung *et al.*, 2012). The first work on *M. oryzae* secretome (Wang *et al.*, 2011) employed a gel-based approach (2-DE and MALDI-TOF-MS, μ LC-ESI-MS/MS) was used to identify 89 differentially expressed spots (14 downregulated and 75 upregulated) in response to N starvation. Functional classification of the identified proteins reveals three main groups, cell wall hydrolase enzyme, protein, and lipid hydrolases, and reactive oxygen species, with a prevalence of proteins containing single peptides (67%). In the second work (Jung *et al.*, 2012), a similar approach (2-DE and nESI-LC-tandem mass spectrometry) was employed by mimicking the early stage of infection in vitro, which led to the identification of 53 nonredundant proteins, including novel and previously known proteins. Further studies on nitrogen starvation on *M. oryzae* were performed using a gel-free approach identifying 5498 proteins. Among these proteins, 363 and 266 resulted as significantly induced or uniquely expressed under nitrogen starved or nitrogen supplemented conditions, respectively (Oh *et al.*, 2017). Functional analysis of protein-induced under nitrogen starvation conditions showed as many metabolic pathways were characterized by an extensive alteration, including the induction of several extracellular proteins.

Furthermore, proteomic studies on *M. oryzae* were also focused on different aspects of fungal lifestyle, including the identification of five novel proteins during the appressorium formation (Sun *et al.*, 2004), or the analysis of differentially regulated proteins in fungal mutants subjected to deletion of a conidial morphology regulating gene called $\Delta com1$ mutant. In the latter case, the comparison between mutant and wild type proteomes leading to the identification of 31 differentially regulated proteins, suggesting as the deleted genes may play a role in several metabolic processes, including the transcriptional reprogramming of genes implicated in melanin biosynthesis (Bhadauria *et al.*, 2010). Both these papers applied a gel-based approach, like the paper of Gokce *et al.*, where a GeLC-MS/MS analysis of conidia allowed the identification of 1500 proteins (Gokce *et al.*, 2011). Afterward, the same research group lately published a second paper on *M. oryzae* conidial proteome, where a gel-free approach was applied for the identification of 2912 proteins (Gokce *et al.*, 2012).

Proteomic studies have also performed on *M. oryzae* proteome to study the effect of plant hormones on mycelium development. In a recently published paper, high inhibitory effects on mycelium development were detected by adding salicylic acid (SA) to mycelium growth media. Authors used a gel-based approach, reporting as a concentration of 100 μ M may reprogram many metabolic pathways, including those related to fungal development, signal transition, stress, and pathogenicity (Wang *et al.*, 2018).

Post-translational modification studies, including glycosylation and phosphorylation, were also performed in *M. oryzae* (Chen *et al.*, 2020; Franck *et al.*, 2015). Glycosylated proteins are widely present at different developmental stages of *M. oryzae*; therefore, a large-scale quantitative gel-free proteomic study (LC-MS/MS-based) was performed to achieve new insight about the functional role of these classes of proteins at different infection stages. A total of 355 unique N-glycosylated proteins were identified, not only the cell wall and plasma membrane proteins but also a wide range of proteins from the secretory pathway with crucial functions in protein glycosylation, folding, quality control, and secretion (Chen *et al.*, 2020).

Phosphoproteome analysis was employed in *M. oryzae* during the developmental process leading to the formation of a well-specialized structure called appressorium. This well-specialized structure is essential for plant infection, allowing the penetration of the plant leaf surface (Howard and Valent, 1996).

By using a gel-free approach, the authors identified a total of 1514 phosphoproteins from different tissues (mycelia, conidia, germinated conidia, and appressoria) from wild type and $\Delta cpkA$ mutant. The functional classification of proteins reveals as multiple changes were observed in the cell wall integrity pathway, thus providing new evidence about the role of this pathway during appressorium formation (Franck *et al.*, 2015).

Concluding Remarks

In conclusion, proteomics, as well as other “omics” tools, represent a robust set of techniques that could actively improve to complement the information of any fungal studies. The recent technical developments allow extending the analysis to the subcellular compartment and post-translational modification, with a focus on the analysis of fungal-environment interaction to addressing important physiological questions related to fungal biology.

New advances in MS-based methods can also represent the basis for develop new probes (antibodies) leading the chance to conjugate proteomics and immunolabelling for protein localization, with the aim to better highlight their biological role in complex biological systems. This is surely a crucial step to decipher the functions and interaction of proteins across different steps of the fungal life cycle, mainly when transformed systems are not applicable.

Introduction

Within the many circumstances in which fungal stress response ability affects human life, the most pressing is when it contributes for their action as human pathogens. Among human pathogenic fungi, *Candida* species, *Cryptococcus neoformans* and *Aspergillus fumigatus* stand out. *Candida* species are the most common cause of invasive fungal infections among hospitalized patients (Wisplinghoff *et al.*, 2004; Perlroth *et al.*, 2007), causing around 750,000 cases of invasive candidiasis each year (Bongomin *et al.*, 2017). *Candida albicans* is the predominant causative agent of invasive candidiasis (Horn *et al.*, 2009; Yapar, 2014), but an increase in the incidence of non-*albicans* *Candida* species has been observed, especially *Candida glabrata* (Pfaller *et al.*, 2010; Taei *et al.*, 2019). *Cryptococcus neoformans* colonization occurs via inhalation, leading to pulmonary infections which may disseminate to cause meningitis, encephalitis or meningoencephalitis. Cryptococcal meningitis is one of the most frequent form of meningitis, with particular impact among HIV patients (Park *et al.*, 2009), 220,000 cases being estimated to occur each year (Rajasingham *et al.*, 2017). Invasive aspergillosis is a serious opportunistic infection that is mainly caused by *Aspergillus fumigatus* (Webb *et al.*, 2018). More than 300,000 cases of invasive aspergillosis occur each year (Bongomin *et al.*, 2017).

Most pathogenic fungi are commensal colonizers of the human body and typically, only cause infections in immunocompromised patients. Both as commensal and pathogens, fungi need to cope and adapt to different stressful conditions in host microenvironments (da Silva Dantas *et al.*, 2016). Fungi like *C. albicans* can colonize a wide variety of human niches (gut, vagina, oral mucosa, skin) where nutrient availability, temperature, pH, and oxygen (O₂) levels differ widely (da Silva Dantas *et al.*, 2016). Additionally, pathogenic fungi are exposed to a wide range of stress factors (Fig. 1). For example: in the oral cavity, kidney and urine they are exposed to osmotic stress (Brown *et al.*, 2014); in the nasopharyngeal environment they face human antimicrobial peptides (AMP), such as histatin-5 (Batoni *et al.*, 2011; Han *et al.*, 2016); in the gastrointestinal and urinary tract pH stress – indeed, the environmental pH inside the human body can be very dynamic: in human blood and tissues the pH is around 7.4, while the gastrointestinal tract can range from pH 2 to pH 8 and in the vagina around pH 4 (Mayer *et al.*, 2013), weak acid stress can also be found in the vaginal fluid, namely, acetic acid thought to be produced by bacteria (Bernardo *et al.*, 2017); once inside a phagocyte, pathogenic fungi are attacked by released reactive oxygen and nitrogen species, therefore, they must have defense mechanisms against those molecules in order to survive (Brown *et al.*, 2014).

In this chapter, the mechanisms of stress response and resistance that enable fungal pathogens to thrive in the human host, and cause deadly infections, are reviewed. Focus is first given to individual stresses faced by these organisms, including oxidative, nitrosative, pH and weak acid stresses, as well as nutrient limitation. Next, the combination of stresses felt by fungal pathogens upon phagocytosis by host immune cells as well as the multifactorial stress protective mechanisms offered by growth as biofilms are discussed.

Response to Nutrient Limitation in Human Host Environments

The ability to tolerate nutrient limitation, especially carbon and nitrogen sources, oxygen and iron, is crucial for successful fungal colonization and infection of the human host.

Carbon Limitation

Upon carbon source limitation, fungal cells rapidly activate a starvation mode, which includes translation downregulation, a shift from glycolysis to gluconeogenesis, and the activation of genes implicated in alternative pathways such as the glyoxylate cycle, and fatty-acid oxidation (Lorenz *et al.*, 2004). In *C. albicans*, when glucose is absent the Csnf1 serine threonine protein kinase, which is essential for viability, is activated and consequently phosphorylates Mig1 preventing its translocation to the nucleus and stopping the repression of alternative carbon source metabolic genes (Van Ende *et al.*, 2019; Petter *et al.*, 1997; Orlova *et al.*, 2008). This drastic metabolic rearrangement allows cells to overcome carbon source depletion using carboxylic acids, amino acids, peptides, N-acetylglucosamine and fatty acids as carbon sources. In fact, the deletion of genes encoding key enzymes of these pathways, for example, *ICL1* (isocitrate lyase) and *FBP1* (fructose-1,6-bisphosphatase) results in attenuated virulence of *C. albicans* in a mouse model, highlighting the importance of these alternative pathways in the ability to overcome the depletion of glucose during infection (Lorenz and Fink, 2001; Ramírez and Lorenz, 2007). Similar mechanisms are also present in *C. neoformans*, including an ortholog of Snf1, the deletion of *CnSNF1* leading to defects in the utilization of alternative carbon sources, but also in the response to nitrosative stress, melanin production and virulence (Hu *et al.*, 2008a). *A. fumigatus* and *C. glabrata* also express Snf1 orthologs, CgSnf1 and Afu2g01700, the later remaining uncharacterized (Fetter and Kwon-Chung, 1996). Besides undergoing

Fig. 1 The multitude of stress sources experienced by fungal pathogens in the human body.

drastic transcriptional remodeling, switching its expression program to genes involved in the utilization of alternative carbon sources, *C. glabrata* is able to use pexophagy, a subtype of autophagy, to recycle intracellular resources and deal with nutrient starvation (Roetzer *et al.*, 2010). Autophagy is a mechanism also used by *C. albicans* (Palmer *et al.*, 2007), *A. fumigatus* (Richie *et al.*, 2007), and *C. neoformans* (Hu *et al.*, 2008b), although it is only a virulence factor for *C. neoformans* and *C. glabrata*.

Beyond metabolic remodeling, nutrient limitation is tackled during tissue invasion by the use of extracellular enzymes to obtain nutrients from the host tissues (Brock, 2009). *C. albicans* secretes 10 aspartic proteases (SAP's, Sap1–10, which are essential for growth when proteins are the sole nitrogen source (Naglik *et al.*, 2003). Similarly, *C. glabrata* expresses 11 cell surface-associated aspartyl proteases (CgYps1–11), called yapsins, which are key virulence factors (Rasheed *et al.*, 2018). *A. fumigatus* also secretes extracellular aspartic proteases, that play a significant role in invasive aspergillosis and are responsible for the hydrolysis of structural proteins in the lungs (Lee and Kolattukudy, 1995), as well as serine proteases and metalloproteases (Abad *et al.*, 2010). Extracellular protease activity was also reported in *C. neoformans* (Chen *et al.*, 1996). Extracellular lipases and phospholipases hydrolyze host triacylglycerols and glycerophospholipids, respectively, resulting in the release of fatty acids, that can be used as sole carbon source (Park *et al.*, 2013). *C. albicans* expresses at least 10 lipases and several phospholipases, of subclasses A–D (Park *et al.*, 2013). *A. fumigatus* phospholipase A–D activity has been detected (Birch *et al.*, 1996), while *C. neoformans* was mainly seen to display phospholipase B activity (Park *et al.*, 2013). *C. glabrata* is able to produce phospholipases (Fatahinia *et al.*, 2017; Sharma *et al.*, 2017; Pandey *et al.*, 2018) however the production is lower than in *C. albicans*, and in some isolates undetectable (Rossoni *et al.*, 2013; Riceto *et al.*, 2015; Canela *et al.*, 2018).

Iron Limitation

When exposed to an iron-poor environment, microorganisms can synthesize siderophores, high-affinity iron chelators that allow them to scavenge iron from the environment. *A. fumigatus* synthesizes four different siderophores, that are essential for virulence (Schrettl *et al.*, 2007). *C. albicans* and *C. glabrata* do not synthesize siderophores, but have one siderophore transporter each, Sit1/Arn1, which enables the uptake of iron bound to siderophores produced by other organisms (Ardon *et al.*, 2001; Heymann *et al.*, 2002; Hu *et al.*, 2002; Bernier *et al.*, 2005; Nevitt and Thiele, 2011). Similarly, *C. neoformans* does not produce siderophores, but is able to use iron chelators produced by other microorganisms (Tangen *et al.*, 2007).

C. albicans is also able to acquire iron from transferrin (Knight *et al.*, 2005), ferritin (Almeida *et al.*, 2008) and hemoglobin, following erythrocyte hemolysis (Almeida *et al.*, 2009). Hemoglobin is then bound by Rbt5 and internalized via endocytosis (Weissman *et al.*, 2008), followed by iron release from the heme group by the heme oxygenase Hmx1 (Santos *et al.*, 2003). *C. neoformans* also uses heme as iron source, in the dependence of Cig1, an exported mannoprotein, Fre2, a cell surface reductase

(Cadieux *et al.*, 2013; Saikia *et al.*, 2014), and several ESCRT proteins (Hu *et al.*, 2013, 2015). *C. glabrata* has a putative hemolysin, Mam3 (Srivastava *et al.*, 2014), however, high hemoglobin concentrations are required for growth to occur based on this iron source (Weissman and Kornitzer, 2004), while, in *A. fumigatus*, this mechanism does not appear to be present.

C. albicans has also a reductive iron-uptake system to scavenge iron from the host environment composed of CaFe10, a cell-surface ferric reductase, and CaFtr1, a ferric iron permease (Cheng *et al.*, 2013). Similarly, in *C. glabrata* extracellular ferric reductases are responsible for the ferric reductase activity, while the complex Fet3–Ftr1 is responsible for the ferrous oxidation and uptake (Srivastava *et al.*, 2014). *A. fumigatus* can also use a reductive iron assimilation pathway involving reduction of ferric to ferrous iron and the uptake of ferrous iron by the FtrA/FetC complex (Schrettl *et al.*, 2004). *C. neoformans* can also use enzymes such as melanin, reductases, and 3-hydroxyanthranilic acid in the reduction of ferric to ferrous iron, which is then imported through a complex involving the permease Cft1 and ferroxidase Cfo1 (Saikia *et al.*, 2014).

In the four pathogenic fungi, a set of transcription factors (TFs) controls the response to nutrient availability, inducing the expression of iron uptake genes and repressing iron consuming processes when facing iron limitation. These include Sef1, Sfu1 and Hap43 in *C. albicans* (Gerwien *et al.*, 2016), Aft1 and Sef1 in *C. glabrata* (Gerwien *et al.*, 2016), SreA and HapX in *A. fumigatus* (Mulvihill *et al.*, 2017) and Cir1 in *C. neoformans* (Kronstad *et al.*, 2013).

C. glabrata has developed also effective iron acquisition strategies and possesses a unique iron homeostasis mechanism. Aft1 is the main transcription factor regulator of this particular mechanism proposed by Gerwien *et al.* (2016), acting as an activator of iron acquisition genes under iron starvation conditions, such as *FTR1*, *FET3* and *SIT1*, at the same time inducing the expression of Cth2 a mediator of posttranscriptional mRNA degradation that will target iron consumption processes transcripts, namely, *HEM15*, *CCP1*, *ACO1*. The transcription factor Sef1, previously mentioned as an important transcriptional activator in *C. albicans* is also a Cth2 target gene in *C. glabrata* which seems to have a specific impact on the TCA cycle and on iron sulfur cluster-containing proteins assembly (Gerwien *et al.*, 2016).

Oxygen Limitation

Oxygen limitation is also an issue in the survival of fungal pathogens in the host, as it is encountered in anaerobic niches of the GI tract or in the inner sections of biofilms (Dumitru *et al.*, 2004). In lab experiments, most pathogenic fungi are unable to grow under anaerobic conditions in minimal medium, since oxygen is required for sterol and unsaturated fatty acid biosynthesis, and consequently, for the maintenance of plasma membrane and cell homeostasis (Lorenz and Parks, 1991). *C. albicans*, for example, is unable to grow in anaerobic conditions in minimal media, unless the medium is supplemented with oleic acid and nicotinic acid (Dumitru *et al.*, 2004).

When under hypoxia, *C. albicans* displays two responses: a short-term response, controlled mostly by the Sit4, Ccr4 and Sko1 TFs (Sellam *et al.*, 2014); and a long-term response which includes the upregulation of ergosterol biosynthesis by the TF Upc2 (MacPherson *et al.*, 2005), induction of fatty acid biosynthesis regulated by Efg1 (Setiadi *et al.*, 2006) and upregulation of glycolysis regulated by Tye7 (Askew *et al.*, 2009). The induction of hyphal formation, and the activation of genes involved in iron metabolism, heme biosynthesis, glycolysis and fermentation, cell wall and membrane remodeling are also observed. Additionally, the TF Ace2 seems to be required for filamentation under hypoxic conditions (Mulhern *et al.*, 2006). More recently, oxygen-sensitive SWI/SNF chromatin remodeling complex was reported as a regulatory circuit controlling metabolic flexibility, stress, commensalism and virulence in *C. albicans*, mutations in this complex affecting the ability to use alternative carbon sources under hypoxia (Burgain *et al.*, 2019).

C. neoformans is a strict obligate aerobe. Nonetheless, this pathogen causes encephalitis and meningoencephalitis, infections in oxygen limited niches, requiring effective hypoxia responses. These are dependent on the TFs Sre1 (a sterol regulatory element binding protein) and Tco1 (Grahl *et al.*, 2012). Under hypoxia, heme biosynthesis, fatty acid metabolism, ergosterol biosynthesis, and stress response transcripts are increased (Chun *et al.*, 2007), while capsule biosynthesis, melanin production, and phospholipase and urease genes are down-regulated (Kong *et al.*, 2017).

A. fumigatus responds to oxygen limitation by upregulating ergosterol biosynthetic genes, cell wall maintenance and glycolysis (Hartmann *et al.*, 2011; Grahl *et al.*, 2012). A particular response of this pathogen is the induction of GABA (γ -aminobutyrate) biosynthesis (Barker *et al.*, 2012), this molecule contributing to glutamate formation and being involved in the prevention of NADH accumulation in the absence of a terminal electron acceptor such as oxygen (Grahl *et al.*, 2012). *A. fumigatus* also has a sterol regulatory element binding protein, SrbA, that seems to regulate the hypoxia response in this pathogen (Blatzer *et al.*, 2011).

Besides mechanisms similar to those referred before, *C. glabrata* is able to import sterols, including cholesterol, under aerobic and anaerobic conditions (Zavrel *et al.*, 2013; Tsai *et al.*, 2004), through the transporter CgAus1 and the mannoprotein CgTir3, under the control of the TF Upc2 (Nakayama *et al.*, 2007; Inukai *et al.*, 2015).

Oxidative Stress Response

Reactive oxygen species secreted by the phagocytes, such as peroxide, superoxide anions, or hydroxyl radicals, induce an oxidative stress response in pathogenic fungi. Fungi can have different levels of intrinsic resistance to oxidative stress: *C. glabrata*, for example, can tolerate over 30 mM hydrogen peroxide (H_2O_2), while *C. albicans* and *A. fumigatus*, only 5 mM (Nikolaou *et al.*, 2009). When subject to oxidative stress fungal cells undergo transcriptional changes regulated by Yap1/Cap1 and Skn7, TFs

responsible for the expression of key genes encoding enzymes required for ROS detoxification, such as superoxide dismutases, catalases, as well as antioxidant molecules (Zadrag-Łęczyńska *et al.*, 2018), this mechanism being present in *C. glabrata* (Roetzer *et al.*, 2011), *C. albicans* (Patterson *et al.*, 2013), *A. fumigatus* (Qiao *et al.*, 2008) and *C. neoformans* (Paul *et al.*, 2015). However, in *A. fumigatus* and *C. neoformans* these TFs are apparently not required for virulence (So *et al.*, 2019).

Superoxide dismutase (SOD) catalyses the conversion of superoxide into H_2O_2 and O_2 . There are four known classes of SODs depending on the cofactor (Mn, Fe, Ni, and Cu-Zn) (Missall *et al.*, 2004a). SODs are present in the majority of the pathogenic fungi, including *C. albicans*, *A. fumigatus* (Holdom *et al.*, 2000), *C. neoformans* (Narasipura *et al.*, 2003) and *C. glabrata* (Roetzer *et al.*, 2011). *C. albicans* has five SOD enzymes, 4 cytosolic (Sod1, Sod3, Sod4, Sod5) and 1 mitochondrial (Sod2) (Missall *et al.*, 2004a). *A. fumigatus* has four SOD enzymes, 1 mitochondrial (Sod2) and three cytoplasmic (Sod1, Sod3 and Sod4). *C. glabrata* and *C. neoformans* express 2 SOD enzymes, 1 cytoplasmic (Sod1) and 1 mitochondrial (Sod2), each (Briones-Martin-Del-Campo *et al.*, 2015; Yang *et al.*, 2017).

Catalases (CAT) catalyze the reduction of H_2O_2 into O_2 and H_2O . In yeasts, there are two types of catalases, catalase T (CatT), present in the cytosol, and catalase A (CatA), present in the peroxisomes and mitochondria, to detoxify H_2O_2 generated during peroxisomal fatty acid β -oxidation and through mitochondrial superoxide dismutation (Zadrag-Łęczyńska *et al.*, 2018). However, *C. albicans* and *C. glabrata* have only one CAT gene, involved in the protection against peroxide stress (Wysong *et al.*, 1998; Cuéllar-Cruz *et al.*, 2008). *A. fumigatus* expresses three catalase enzymes, one is produced by conidia, and two by mycelia, which confer protection against host oxidative stress (Paris *et al.*, 2003). In *C. neoformans* four CAT enzymes were identified, 2 located in spores (Cat1 and Cat3), 1 peroxisomal (Cat2) and 1 cytosolic (Cat4), but surprisingly, quadruple catalase mutants are not susceptible to oxidative stress (Giles *et al.*, 2006).

Other enzymes such as glutathione peroxidases can replace the function of catalases, reducing H_2O_2 by using glutathione as the electron donor. In this mechanism oxidation of glutathione by glutathione peroxidases results in the formation of disulfide glutathione, that in turn is reduced again by glutathione reductases, using NADPH as the reducing agent (Miramón *et al.*, 2014). In *C. albicans*, three enzymes with glutathione peroxidase activity were reported, gpx31, gpx32, and gpx33 (Miramón *et al.*, 2014). *C. glabrata* has one glutathione peroxidase, Gpx2 (Roetzer *et al.*, 2011). *C. neoformans* contains two glutathione peroxidases, Gpx1 and Gpx2 (Grant, 2001). In *A. fumigatus* this type of enzymes has not been reported.

Finally, glutaredoxins and thioredoxins, are redox scavenging molecules, that together with glutathione, contribute to protect and repair oxidized proteins (Cuéllar-Cruz *et al.*, 2014). *C. albicans* has four glutaredoxin encoding genes (Chaves *et al.*, 2007), while *C. neoformans* expresses one glutaredoxin, Grx4, important in iron sensing and virulence (Attarian *et al.*, 2018). In the remaining pathogenic fungi, the role of glutaredoxins in this response has not been sufficiently studied. Thioredoxin activity relies on the action of thioredoxin peroxidases, such as Tsa1, which, in *C. albicans*, is important for H_2O_2 neutralization (Shin *et al.*, 2005), while in *C. neoformans* it confers oxidative and nitrosative stress resistance (Missall *et al.*, 2004b). *A. fumigatus*, has three thioredoxin peroxidases, one cytosolic, Prx1, and two mitochondrial, PrxB and PrxC, Prx1 conferring oxidative stress resistance (Rocha *et al.*, 2018). *C. glabrata* expresses two thioredoxin reductases, Tsa1 and Tsa2 (Roetzer *et al.*, 2011).

If *C. albicans* (Palmer *et al.*, 2007), *C. glabrata* (Roetzer *et al.*, 2011), *A. fumigatus* (Richie *et al.*, 2007), or *C. neoformans* (Hu *et al.*, 2008b) cells are unable to deal with the imposed oxidative stress, the cell cycle is delayed in order to enable DNA-damage repair and the activation of cellular degradation systems occur (autophagy and ubiquitin-dependent proteasome system) as an attempt to remove damaged or unnecessary proteins and organelles and restore internal homeostasis. If the cell is unable to recover, programmed cell death is activated (Zadrag-Łęczyńska *et al.*, 2018).

Nitrosative Stress Response

Reactive nitrogen species (RNS), such as nitric oxide (NO), produced by the innate immune system, can cause molecular damage in DNA, proteins and lipids of an invading microorganism (Hromatka *et al.*, 2005). Flavohemoglobin is one of the most frequent enzymes used by bacteria and eukaryotes to fight nitrosative stress (Hromatka *et al.*, 2005). This enzyme is responsible for the detoxification of NO under aerobic conditions. S-nitrosothiol (GSNO) reductase, responsible for the metabolism of the products resulting from the reaction of NO with thiol compounds, is another enzyme often involved in that response. *C. albicans* expresses three flavohemoglobin-related proteins, Yhb1, Yhb4 and Yhb5, and also a GSNO, Fdh3 (Tillmann *et al.*, 2015). YHB1 is induced in response to NO stress and its deletion results in increased sensitivity to NO (Ullmann *et al.*, 2004). In *C. glabrata* nitrosative response lacks further studies. No GSNO reductase has been identified, however this yeast has an ortholog of CaYHB1 described as a putative flavohemoglobin (Merhej *et al.*, 2015). *C. neoformans* has both enzymes, GSNO reductase encoded by GNO1 and flavohemoglobin encoded by FHB1, both required for the pathogenicity of this organism (De Jesús-Berrios *et al.*, 2003). In *A. fumigatus*, two genes encoding flavohemoglobins and one encoding a GSNO reductase were identified, however, they seem not to be involved in the nitrosative response (Lapp *et al.*, 2014); this pathogen is likely to have other yet unknown mechanisms to deal with NO stress.

pH Stress Response

The different niches in the human body have very variable pH values, ranging from pH 2 to pH 8 (Mayer *et al.*, 2013) thus being important for microorganisms to have mechanisms to deal with this variability.

Under pH stress, cytosolic pH neutrality is maintained through the activity of plasma membrane H^+ :ATPase, encoded by *PMA1* gene in *A. fumigatus* (Burghoorn *et al.*, 2002), *C. albicans* (Monk *et al.*, 1991), *C. glabrata* (Bairwa and Kaur, 2011), and *C. neoformans* (Farnoud *et al.*, 2014), and vacuolar H^+ :ATPase (vATPase) complex, also present in all species. When cell energy reserves are depleted, the cell loses ability to maintain its intracellular pH leading to protein misfolding and eventually cell death (Skoneczny and Skoneczna, 2018). Alternative mechanisms to overcome pH stress include, in *C. glabrata*, the remodeling of plasma membrane fatty acid and sterol composition, affecting H^+ ATPase activity, under the control of CgMed15B and CgMed3 mediator complex components (Qi *et al.*, 2017; Lin *et al.*, 2017). The TF CgRds2 is also involved in acidic pH stress response, its deletion resulting in decreased intracellular ATP content, membrane permeability and cell survival (Wu *et al.*, 2020), while the yapsin CgYps1 was also found to be essential for survival in an acidic environment, being required for cell wall remodeling, reducing the total β -glucan content (Bairwa and Kaur, 2011). *C. albicans* has a remarkable ability to modulate extracellular pH, being capable to change an acidic or alkaline extracellular pH to neutral pH in just 12 h (Vylkova and Lorenz, 2014). In such conditions, *C. albicans* is able to use amino acid or carboxylic acids like pyruvate, α -ketoglutarate, or lactate as carbon source and generate ammonia as a byproduct, neutralizing acidic environments (Vylkova *et al.*, 2011; Danhof *et al.*, 2016).

Alkaline pH medium, on the other hand, destroys the proton gradient across the plasma membrane, inhibiting important nutrient exchanges, such as glucose, phosphate and metals. In fungi, response to alkaline pH is generally mediated by the Rim101/PacC signaling pathway, controlling Na^+ and Li^+ homeostasis and vATPase activity, while Rim9, Rim21 and Rim8 are involved in the external pH sensing (Garnaud *et al.*, 2018; Bertuzzi *et al.*, 2014; Ost *et al.*, 2015). In *C. albicans* Rim101 signaling pathway seems to act in integration with the calcineurin/Crz1 pathway, since upon alkaline stress an immediate calcium influx occurs in this yeast (Wang *et al.*, 2011). *C. glabrata* has a *RIM101* ortholog, however, this pathway remains uncharacterized.

Weak Acid Stress Response

Weak organic acids are frequently used in the food industry as preservatives, but are also used as herbicides, antimalarial, anticancer and immunosuppressive drugs (Mira *et al.*, 2010). In low pH environments, these compounds are typically found in their undissociated state allowing them to diffuse through the fungal plasma membrane. After entering the cells, these acids dissociate, leading to the release of protons, which will result in cytosolic acidification. Additionally, acid dissociation, leads to the accumulation of the corresponding anionic conjugated bases, which are charged and therefore cannot simply diffuse back out (Skoneczny and Skoneczna, 2018). Cell responses to various weak organic acids seems to be different (Mira *et al.*, 2010). Response to sorbic or benzoic acids involves the plasma membrane H^+ -ATPase, but also the up-regulation of the ATP-binding cassette (ABC) anion efflux pump Pdr12 (Ullah *et al.*, 2012), under the control of the TF War1 in *S. cerevisiae* (Schüller *et al.*, 2004), *C. albicans* (Lebel *et al.*, 2006), and *C. glabrata*. Interestingly, in *C. glabrata* sorbic acid stress activates the MAP kinase Hog1, which is required for *PDR12* overexpression (Jandric *et al.*, 2013). There are not many studies on this type of response in *A. fumigatus*, however, very recently, WarA (similar to War1) was characterized in *A. fumigatus*, and was shown to be required for resistance to weak-acid (Geoghagan *et al.*, 2020). No War1 homologs were found in *C. neoformans*. The response to short-chain weak acids, such as acetic acid, on the other hand, is mostly controlled by the TF Haa1. In *C. glabrata*, this TF controls the expression of 75% of the genes activated under acetic acid stress, including *PMA1* and the proposed acetate exporter gene of the Drug: H^+ Antiporter (DHA) family, *TPO3* (Bernardo *et al.*, 2017). Additional DHA proteins found to play a role in acetic acid resistance include Aqr1 (Costa *et al.*, 2013) and CgDtr1, the later contributing to *C. glabrata* proliferation upon phagocytosis and virulence (Romão *et al.*, 2017). In *C. albicans* the regulator of this response seems to be the TF Mnl1, which regulates weak acid stress responses acting antagonistically with the Nrg1 TF. Indeed, it was shown that the deletion of *MNL1* prevents the long-term adaptation of *C. albicans* cells to weak acid stress and compromises their global transcriptional response under these conditions (Ramsdale *et al.*, 2008).

Response to Stress During Phagocytosis

Upon phagocytosis, pathogens are subjected to a panoply of antimicrobial mechanisms in the phagosome environment. Genome-wide and phenotypic screenings from engulfed pathogens have provided a sneak peek into the antimicrobial mechanisms applied by phagocytes. Major stresses associated with phagocytosis include nutrient limitation (carbon, nitrogen, iron), oxidative and nitrosative stress and low pH stress (Flannagan *et al.*, 2012; Pais *et al.*, 2019a,b). Besides adapting their metabolic responses to the phagosome environment, successful pathogens have developed sophisticated strategies to escape immune cells (Fig. 2).

A comprehensive response to low nutrient availability typically results in reprogrammed metabolic settings focused on energy generation from alternative carbon sources. Phagocytosed *Candida* display changes in carbon/energy metabolism which are focused on the activation of gluconeogenesis, alternative energy production pathways (e.g., glyoxylate cycle) and degradation of fatty acids for utilization as carbon source (Lorenz and Fink, 2001; Lorenz *et al.*, 2004; Fradin *et al.*, 2005; Kaur *et al.*, 2007; Rai *et al.*, 2012; Muñoz *et al.*, 2019; Williams and Lorenz, 2020). This is generally accompanied by downregulation of other pathways, such as plasma membrane and cell wall biosynthesis due to shutdown of sterol metabolism and mannan or glucan metabolism, respectively (Roetzer *et al.*, 2008; Fukuda *et al.*, 2013; Muñoz *et al.*, 2019). *C. neoformans* activates the cAMP/protein kinase A pathway, peroxisome function, lipid metabolism and membrane transport (Fan *et al.*, 2005). Similarly, *A. fumigatus* displays activation of fatty acid oxidation, transport functions and nutritional response genes, while genes involved in fermentation are

Fig. 2 Fungal pathogens response and escape mechanisms upon phagocytosis. Pathogens are engulfed by phagocytes into early phagosomes that undergo a maturation process accompanied by a decreased pH in the late phagolysosome. Pathogens are submitted to multiple stresses and respond in a concerted action. Common responses across fungal pathogens include reprogrammed energy metabolism (response to nutrient limitation), modulation of reactive species production (response to ROS/RNS stress) and inhibition of phagolysosome acidification (response to low pH). After surviving the harsh phagolysosome environment, fungal pathogens typically apply passive escape mechanisms based on overgrowth inside the phagocyte (*C. glabrata*, *C. neoformans*) or non-lytic exocytosis (*C. albicans*, *C. neoformans*); or active escape mechanisms based on filamentous growth (*C. albicans*, *A. fumigatus*).

down-regulated (Morton *et al.*, 2011). As for nitrogen metabolism, the same response pattern is adopted by fungal pathogens. Phagocytosis usually results in the induction of protein degradation pathways and amino acid biosynthesis (Kaur *et al.*, 2007; Morton *et al.*, 2011; Fukuda *et al.*, 2013; Williams and Lorenz, 2020). Recently, biotin metabolism was also correlated with *Candida* proliferation and virulence (Sprenger *et al.*, 2020). Additional strategies also include the activation of mechanisms to capture extracellular nutrients. A hallmark example is iron acquisition mechanisms, as iron is sequestered from pathogens by host scavengers and transporters (Cellier *et al.*, 2007; Almeida *et al.*, 2009; Haas, 2014). Iron limitation results in the activation of iron acquisition pathways and shutdown of iron consuming ones (Srivastava *et al.*, 2015; Gerwien *et al.*, 2016) and correlates with iron homeostasis genes that are required for survival after phagocytosis (Seider *et al.*, 2014). Furthermore, autophagy and pexophagy upon phagocytosis are yet additional mechanisms applied by *Candida* and *C. neoformans* to sequester resources in a poor-nutrient environment (Fan *et al.*, 2005; Oku and Sakai, 2010; Roetzer *et al.*, 2010, 2011; Till *et al.*, 2012; Fukuda *et al.*, 2013).

Response to oxidative stress includes detoxification of the correspondent reactive species (Goldman *et al.*, 2000; Shao *et al.*, 2005; Fukuda *et al.*, 2013). Besides reactive species detoxification, pathogenic response also includes additional mechanisms, such as cell wall composition and cytokine production, which have been associated with oxidative stress resistance and macrophage survival in *C. glabrata* (Seider *et al.*, 2014). Another crucial response to reactive species is the modulation of their production, which has been observed in *Candida*, *C. neoformans* and *A. fumigatus*, and includes both ROS and RNS production modulation (Goldman *et al.*, 2000; Orciuolo *et al.*, 2007; Seider *et al.*, 2014; Salvatori *et al.*, 2018; Schmidt *et al.*, 2018). In some pathogens, interference with reactive species production has been associated with particular structures or metabolites. The capsule of *C. neoformans* plays a role in response to reactive species, as it helps to quench free radical bursts (DeLeon-Rodriguez and Casadevall, 2016), while the melanin pigment and the toxin gliotoxin produced by *A. fumigatus* contribute to the modulation of ROS production (Orciuolo *et al.*, 2007; Schmidt *et al.*, 2018).

Response to low pH occurs as a reaction to phagosome acidification. After pathogen phagocytosis, intracellular compartments known as phagosomes are created. The phagosome goes through a maturation process accompanied by acidification ranging from pH 6.0 in the initial endosomes to pH 4.5 in the final phagolysosomes. This contributes for a stressful environment, especially when combined with the activity of hydrolytic enzymes (Vieira *et al.*, 2002; Seider *et al.*, 2011). Distinct approaches to cope with this antimicrobial mechanism have been described. In *C. glabrata* response to low pH includes the activation of stress responses, as well as carbohydrate and amino acid metabolic pathways whereas glucose metabolism and cell wall proteins are downregulated

(Bairwa and Kaur, 2011; Wu *et al.*, 2015; Lin *et al.*, 2017). Likewise, *C. albicans* uses catabolism of amino and carboxylic acids to neutralize acidic environments and also resorts to N-Acetylglucosamine (GlcNAc) metabolism to combat phagolysosome acidification (Vylkova and Lorenz, 2014; Danhof *et al.*, 2016; Miramón and Lorenz, 2016; Vesely *et al.*, 2017). The acidic pH in the phagolysosome further favors the filamentation of *C. albicans* (Káposzta *et al.*, 1999), leading to macrophage evasion (Lorenz *et al.*, 2004). The inhibition of phagolysosome maturation and acidification is also a strategy reported in *C. glabrata*, *C. neoformans* and *A. fumigatus* (Seider *et al.*, 2011; DeLeon-Rodriguez and Casadevall, 2016; Schmidt *et al.*, 2018). This is consistent with findings showing an acidic pH is key for *A. fumigatus* killing (Ibrahim-Granet *et al.*, 2003). As for *C. neoformans*, seemingly contradictory results have been described. One study describes inhibition of phagosome acidification (Smith *et al.*, 2015), while another study found a lack of it (Levitz *et al.*, 1999).

The aforementioned strategies mainly represent metabolic responses to counteract stresses exerted in the phagosome and maintain pathogen cell viability. In addition to intracellular survival, fungal pathogens also employ strategies aimed at phagocyte escape. This can be typically achieved by two avenues: hyphal growth leading to phagocyte piercing, or intracellular growth of the pathogen leading to phagocyte lysis. The strategy used depends partially on the ability of the pathogen to display filamentous growth. *C. albicans* enters the host in yeast form but can produce hyphae in response to host physiological conditions. Using a similar approach upon phagocytosis, *C. albicans* induces pyroptotic cell lysis of macrophages (Uwamahoro *et al.*, 2014; Wellington *et al.*, 2014) and at later stages undergoes a morphogenic transformation from yeast to filamentous form, coupled with cell wall remodeling (Muñoz *et al.*, 2019), that mediates phagosome damage and membrane piercing (Jiménez-López and Lorenz, 2013; Westman *et al.*, 2018). Moreover, the cytolytic peptide Candidalysin further contributes to phagocyte cell death (Kasper *et al.*, 2018). Other than damaging the phagocyte structure, *C. albicans* can also escape via non-lytic exocytosis (Bain *et al.*, 2012). As a filamentous fungus, *A. fumigatus* shares much of these traits, entering the host as conidia that subsequently germinate to establish an infection. Upon phagocytosis, conidia are able to germinate in the late phagosome leading to phagocyte necrosis (Wasylnka *et al.*, 2005; Shah *et al.*, 2016). *A. fumigatus* also produces toxins that induce immune cell death (Morton *et al.*, 2012) and due to the production of melanin, *A. fumigatus* conidia can avoid killing by phagocytes, deregulate immune homeostasis and interfere with apoptosis (Chamilos *et al.*, 2016; Mohebbi *et al.*, 2016; Sprengeler *et al.*, 2016; Kymizi *et al.*, 2018).

On the other hand, species like *C. glabrata* or *C. neoformans* do not form hyphae and exist only in yeast form. As a consequence, immune evasion is based on cell surface alterations, such as cell wall remodeling in *Candida* (Kaur *et al.*, 2007) or capsule antiphagocytic properties in *C. neoformans* (Del Poeta, 2004; Chrisman *et al.*, 2011; Bojarczuk *et al.*, 2016). However, once phagocytosed, these species employ an escape strategy based on intracellular growth and consequent lysis of the phagocyte (Seider *et al.*, 2011; Dementhon *et al.*, 2012; García-Rodas and Zaragoza, 2012; Coelho *et al.*, 2014). *C. neoformans* can also escape by non-lytic exocytosis (Alvarez and Casadevall, 2006; Ma *et al.*, 2006; Nicola *et al.*, 2011). This strategy implies the ability not only to survive the harsh environment of phagosome, but also to replicate inside it (Tucker and Casadevall, 2002; Seider *et al.*, 2011). In fact, both species were also proposed to use immune cells as “Trojan horses” for dissemination (Charlier *et al.*, 2009; Brunke and Hube, 2013; Duggan *et al.*, 2015).

Biofilm Formation as a Stress Response

Biofilm is a structure defined by an agglomerate of microorganisms attached to a given surface and protected by an extracellular matrix (Costa-Orlandi *et al.*, 2017). The formation of biofilms is a complex and multistage process that both bacterial and fungal microorganisms employ for their survival (Acker *et al.*, 2014), being their most common type of growth (Martinez and Fries, 2010). This process starts with the adhesion of the microorganisms to the chosen surface, following the production of extracellular polymeric substances, such as polysaccharides, proteins, lipids and DNA, which are secreted for the formation of the extracellular matrix, a gel like structure that allows firmer attachment and a consolidated architecture (Flemming and Wingender, 2010).

Fungi are able to develop yeast or filamentous biofilms. *Candida albicans* is able to form a filamentous biofilm with water channels that allow the flux of nutrients, while *Candida glabrata* forms a compact yeast-cell biofilm (Silva *et al.*, 2009), with half of the thickness of *C. albicans* biofilms (Kucharíková *et al.*, 2014). *Candida* species infections in the human host are usually linked to biofilm formation in preferable niches, like the vaginal tract (Harriott *et al.*, 2010; Nett, 2016). In turn, *C. neoformans* biofilm formation consists in the development of microcolonies of clustered cells, combined with capsular polysaccharide fibers and extracellular material (Martinez and Casadevall, 2006a,b), which can be developed after the fungus cross the blood brain barrier, being called cryptococcoma (Aslanyan *et al.*, 2017). The biofilm formed by *A. fumigatus* in the human host is denominated as aspergilloma, a spherical mass of hyphae that can be developed in an immune competent host, but requires a pre-existing cavity, generally from a previous tuberculosis in the respiratory tract. The filamentous biofilm of *A. fumigatus* has some similarities to the one developed by *C. albicans*, with channels between hyphae for the passage of fluids and nutrients (Ramage *et al.*, 2011). All these species are able to form biofilms on abiotic surfaces used on medical-devices (Walsh *et al.*, 1986; Hawser and Douglas, 1994; Ramage *et al.*, 2011; Susewind *et al.*, 2015), and yeast cells/spores from these biofilms are able to detach themselves and enter the blood stream, causing disseminated fungal infections (Costa-Orlandi *et al.*, 2017). Biofilms are thus a microbial strategy to invade and persist within the human host, being approximately 65% of all infections believed to be related to biofilms (Martinez and Fries, 2010; Acker *et al.*, 2014).

Interestingly, biofilms are also used as a stress response by pathogenic fungi (Fig. 3). This protective structure has been observed to confer resistance to different host-imposed stresses. For instance, *C. albicans* biofilm formation is stimulated by the presence of

Fig. 3 Implications of biofilm formation in response to stress in (A) *Candida albicans*, (B) *Candida glabrata*, (C) *Cryptococcus neoformans* and (D) *Aspergillus fumigatus*.

peripheral blood mononuclear cells (PBMCs), enriched in monocytes and macrophages. Biofilm formation at such conditions leads to the accumulation of PBMCs in the basal and middle layers of the biofilm, without phagocytosis events, but with the release of differential levels of pro- and anti-inflammatory cytokines (Chandra *et al.*, 2007), allowing a clear modulation of the host immune response. *C. neoformans* biofilms are also linked to a strategy to evade phagocytosis. *C. neoformans* cells exit macrophages in biofilm-like microcolonies, being aggregated by a polysaccharide matrix (Alvarez *et al.*, 2008), suggesting that the formation of this biofilm-like structure allows this fungus to break free from macrophages.

Moreover, *C. neoformans* biofilms have been shown to increase the tolerance of this fungal pathogen to thermal stress (either higher or colder temperatures), to UV irradiation and to the presence of lactoferrin, an effector molecule of the innate immune system (Martinez and Casadevall, 2005, 2007). In addition, cryptococcal biofilm cells are more resistant against oxidative stress and defensins than planktonic cells (Martinez and Casadevall, 2006a,b), exhibiting increased expression of several oxidative stress response genes (Santi *et al.*, 2014). Using the *Galleria mellonella* model of infection, *C. neoformans* cells in biofilms were shown to be more virulent than planktonic cells, being more equipped against the larvae innate immune system (Benaducci *et al.*, 2016).

The tolerance fungal biofilms present to different stresses may rely on specific characteristics of this protective structure. One specific part of fungal biofilms that is intrinsically related to the response to external stresses is the extracellular matrix. Although the composition of the extracellular matrix may differ between *Candida* species, *C. neoformans* and *A. fumigatus* (Gibbons *et al.*, 2011), its protective role is unmistakable. One extracellular matrix component important for stress resistance is the galactosaminogalactan (GAG) of *A. fumigatus* biofilms. GAG is a component found not only to mediate adherence, but also to mask β -1,3-glucans (avoiding recognition by the host immune system) and induce the interleukin-1 receptor antagonist (IL-1Ra) that blocks proinflammatory IL-1 signaling (Loussert *et al.*, 2010; Gravelat *et al.*, 2013; Gresnigt *et al.*, 2014). Similarly, *C. neoformans* produces glucuronoxylomannan (GXM), an essential component of the extracellular matrix (Martinez and Casadevall, 2005). Interestingly, certain specific antibodies against GXM have been found to decrease the pharmacological activity of antifungal drugs against *C. neoformans* biofilms (Martinez *et al.*, 2006). This component also present in the capsule of *C. neoformans* has been linked to the creation of electrostatic repulsive forces to avoid phagocytosis (Aslanyan *et al.*, 2017).

Moreover, several studies show how different antifungal drugs have less effect upon biofilms thanks to the presence of this gel-like matrix (Martinez and Casadevall, 2006a,b). For instance, *C. albicans* and *C. glabrata* biofilms have shown to rely on β -1,3-glucans of the extracellular matrix to sequester antifungal drugs, such as fluconazole (Nett *et al.*, 2007, 2010a,b; Mitchell *et al.*, 2013). *C. albicans* biofilms also count with extracellular DNA from the extracellular matrix, which has been linked to higher resistance towards antifungal drugs (Martins *et al.*, 2012). Likewise, in *A. fumigatus* biofilms, the extracellular matrix has also been identified as the cause of polyenes resistance, thanks to its extracellular DNA, which is also essential for the integrity of the biofilm (Beauvais *et al.*, 2007; Rajendran *et al.*, 2013). Nevertheless, it is important to notice that the extracellular matrix may not be the only aspect of biofilms allowing antifungal resistance. The upregulation of multidrug resistance transports in *C. albicans*, *C. glabrata* and *A. fumigatus* biofilms (*CaCDR1*, *CaCDR2*, *CaMDR1*, *CgTPO1_2*, *CgQDR2*, *AfMDR4*), without exposure to antifungal drugs

(Ramage *et al.*, 2002; Nett *et al.*, 2009; Gibbons *et al.*, 2011; Santos *et al.*, 2020), may be the reason for the intrinsic antifungal resistance of biofilm cells. Such upregulation indicates that these transporters are needed for the normal development of fungal biofilms. In fact, *C. glabrata* found to rely on CgDtr1, CgTpo4, CgTpo1_2 and CgQdr2 Drug: H⁺ antiporters for maximum formation of biofilms (Santos *et al.*, 2020). These transporters were found to alter the plasma membrane potential, as well as the expression of certain adhesin-encoding genes, being believed to control the nutrient availability influencing biofilm formation (Santos *et al.*, 2020). In addition, CgDtr1 has been linked to the resistance against oxidative and acetic acid stresses, being necessary for the full virulence of *C. glabrata* in the *G. mellonella* model of infection (Romão *et al.*, 2017).

Other effectors within *C. albicans* biofilms are responsible for the response to oxidative stress, like the superoxide dismutase's Sod4 and Sod5, which fight ROS generated by the presence of antifungal drugs, like miconazole (Bink *et al.*, 2011). In addition, fungal biofilms harbor the so called persister cells, a clonal subpopulation of cells that exhibit high tolerance to antimicrobial drugs. This subpopulation does not appear in planktonic conditions, contrary to what happens in bacterial populations. In fungi, persister cells seem to emerge due to the attachment of fungi to a surface, in the first step of biofilm formation (Lafleur *et al.*, 2006).

Conclusions

Pathogenic fungi are exposed to host microenvironments and need to cope and adapt to different stressful conditions therein. Response to nutrient limitation, including carbon, nitrogen, metals, and oxygen, is a prerequisite for successful fungal colonization and infection of the human host. The response to these starvation conditions is generally conserved among fungi, however, some pathogens have acquired specific mechanisms, for example, the production of their own siderophores by *A. fumigatus*, instead of importing them from the environment, or the import of sterols under anaerobic conditions by *C. glabrata*.

Multiple stress combinations, such as those felt after engulfment by phagocytes, are even more challenging that the sum of individual stresses. Response to these multi-stress environments include adaptation to nutrient limitation, to ROS and RNS and to acidification, but also, if possible, deployment of evasion strategies. Evasion mechanisms differ between fungal pathogens, *C. albicans* and *A. fumigatus* relying on filamentous growth, while *C. albicans* and *C. neoformans* using non-lytic exocytosis.

Another key protection mechanism used by fungi is biofilm formation. This feature is clearly used by the four pathogens considered in this chapter, although the structure and composition of the biofilm and its matrix varies from species to species. Despite their differences, fungi use biofilms as a strategy to evade phagocytosis, while providing protection against host stress factors or even antifungal drugs.

Although, generally speaking, fungal defense mechanisms against individual host stresses are reasonably characterized, some species-specific mechanisms, especially for multi-stress responses, remain unknown. A better understanding of, for example, the alkaline pH signaling pathway of *C. glabrata*; weak acid stress response in *C. neoformans* and *A. fumigatus*; nitrosative stress response in *C. glabrata* and *A. fumigatus*, are still required. Additionally, further studies on the use of alternative nutrient sources by pathogens may be necessary to fully understand their mechanisms of survival within phagocytes. All this knowledge will be crucial to design new and more effective strategies to fight life-threatening infections caused by very well adapted, stress resistant, fungal pathogens.

Introduction

The world population is growing at exponential rate. Consequently, a number of anthropogenic activities have adverse effects on ecosystems and life on the planet. Industrialization, overuse of agrochemicals, and untreated industrial and municipal waste, as well as discharge of toxic effluents to the environment, are causing continuing damage to soil and water. Hence there is an urgent need to reverse and cure the hazardous pollutants negative impacts. One approach thereto is bioremediation of toxic organic chemicals.

Bioremediation involves exploitation of biological systems – plants, algae, bacteria, or fungi – for the purpose of removing or degrading and detoxifying pollutants (Alexander, 1994; Arora, 2018; Pande *et al.*, 2020). As vigorous decomposers, fungi hold promise for the removal of numerous xenobiotics from contaminated soil and water in an efficient, environmentally acceptable, and cost-effective manner, and thus could function as mycoremediation agents. Filamentous fungi have several distinctive properties that lend them advantages in bioremediation: fungal mycelial network and hyphal tips directional growth enable them to search out and penetrate new yet non-colonized, non-soluble substrates as sources of nutrients and energy; the multicellular fungal colony can function as an organism, recycle dead hyphae, and translocate resources; the mycelium of several fungi form rhizomorphs are able to grow through large distances of unfriendly environment, and thus establish in new niches relatively far from the colony source; fungi can survive, grow, and develop under toxic and stressful conditions (Baldrian, 2008; Sardrood *et al.*, 2013; Treu and Falandysz, 2017; Akhtar and Mannan, 2020; Ferreira *et al.*, 2020; Pölme *et al.*, 2020). This chapter focuses on a specific group of wood decay fungi that cause white rot.

White Rot Fungi: The Lignin-Degrading Fungi

White-rot fungi belong to the *Basidiomycetes*, mostly saprotrophic in the wild, where they grow readily on woody substrates. However, they do not form a taxonomic, but rather a physiological group based on their unique ability to efficiently degrade all plant cell wall components, including the most recalcitrant component: lignin. This property is the result of their producing several types of extracellular oxidizing enzymes that comprise the lignin degradation system (Kirk and Farrell, 1987; Hatakka, 1994; Hammel and Cullen, 2008). These fungi are termed “white rot” due to the removal of the brown lignin, giving the residual decayed wood a white appearance. Another group of wood decay fungi are the brown rots, which specialize in degradation of cellulose despite the presence of lignin. However, based on genomic analyzes of 22 wood decay fungi, Riley *et al.* (2014) demonstrated a continuum rather than a dichotomy between these two processes of wood decay. Riley’s findings were further confirmed by phenotypic and genomic analyzes of many additional wood decay fungi, citing the complexity of the WRF ligninolytic system and its evolution (Nagy *et al.*, 2017; Schilling *et al.*, 2020). It has been suggested that these fungi originated in the Paleozoic area, evolved about 300 million years ago, and probably overlapped with the end of the Carboniferous period (Floudas *et al.*, 2012).

The biodegradation of the recalcitrant lignin is a central process in the global carbon cycle that enables further utilization of the resulting carbohydrates. The lignin role in woody plants is to provide rigidity as well as physical and chemical shield, thus providing passive defense from attack by most microorganisms. The lignin polymer is derived mainly from three aromatic alcohol monomers that differ in their degree of methoxylation: p-coumaryl, coniferlyl, and sinapyl alcohols. These units are linked together into a three-dimensional polymer via radical coupling reactions resulting in a complex and heterogeneous network of aromatic polymers containing ether and C-C and C-O linkages (Boerjan *et al.*, 2003; Vanholme *et al.*, 2010).

In accordance with the lignin nonspecific structure, the WRF enzymatic degrading system consists of nonspecific oxidative reactions leading to its depolymerization and mineralization. Its capability of degradation of a wide range of toxic aromatic pollutants, the subject of the current review, originates from these enzymes activities. Their non-specific nature and exceptional oxidation potential likely force the fungi to rapidly secrete oxidizing enzymes to avoid damage to the cells. Indeed, these enzymes are known to function in the extracellular environment. The ligninolytic system includes several families of enzymes: Lignin peroxidases (LiP), Manganese peroxidases (MnP), Versatile peroxidases, (VP), Dyeperoxidase (DyP), Phenol oxidases, and Laccases. Also of importance are H₂O₂-producing enzymes, as they provide the peroxide to the peroxidases. These are Glyoxal oxidase (GLOX), Aryl alcohol oxidase (AAO), Vanillyl alcohol oxidase, and Cellobiose dehydrogenase (CDH). These enzymes biochemistry, physiology, genomics, and genetics have been studied and reviewed in detail over the years (Kirk and Farrell, 1987; Hatakka, 1994; Martinez *et al.*, 2005; Hofrichter *et al.*, 2010; Hadar and Cullen, 2013; Knop *et al.*, 2015; Kües, 2015). Besides the ligninolytic system, additional physiological functions are involved in growing on wood, such as intracellular transport and detoxification of aromatic toxic products released during wood utilization, i.e., families of transporters, cytochrome p450 monooxygenases (CYP450), and glutathione-S-transferases (Syed and Yadav, 2012; Morel *et al.*, 2013; Deroy *et al.*, 2015;

Nagy *et al.*, 2017; Daly *et al.*, 2020). These enzymes are very common in WRF and play an important and central role in detoxification of numerous organic pollutants. More recently, developments in the study of lignin degrading and modifying enzymes as well as barriers and challenges to practical use of these enzymes were reviewed (Kües, 2015; Biko *et al.*, 2020; Chan *et al.*, 2020; Asemoloye *et al.*, 2021).

Among the wide variety of WRF species in nature, only a few have received in-depth attention from the scientific community. Some of their characteristics have been studied in more detail, including enzymatic mechanisms of wood degradation, the ligninolytic system, and biotechnological applications such as biofuel production, as well as pollutant degradation. Here are three representative examples:

Phanerochaete chrysosporium Burdsall

This WRF is the first and most studied organism owing to its lignin biodegradation and mineralization capabilities, and is considered a model fungus. *P. chrysosporium* is a crust fungus, which forms flat, fused reproductive fruiting bodies on woody surfaces. It is thermotolerant and grows relatively fast at 42°C. It was isolated and described in the Sonoran Desert in 1971 (Burdsall and Eslyn, 1974). The enzymes lignin peroxidase and Mn-peroxidase were discovered while investigating lignin degradation mechanisms in *P. chrysosporium* (Glenn *et al.*, 1983; Tien and Kirk, 1983) and it was suggested to be used for organic pollutants bioremediation (Bumpus *et al.*, 1985). *P. chrysosporium* was the first WRF to be sequenced (Martinez *et al.*, 2004).

Trametes (Coriolus) versicolor (L.) Lloyd (“Turkey Tail”)

This WRF has distinct morphological features, including concentric multicolored zones on the upper side of the cap. It grows on many deciduous trees (oaks) and some conifers (firs and pines), with the fruiting body appearing on stubs and trunks year round in temperate Asia, North America, and Europe. It is known for its medicinal value as used in Chinese traditional medicine, and contains general health-promoting effects (Hiscox *et al.*, 2010; Habtemariam, 2020).

Pleurotus ostreatus (“Fries”) Kummer (“Oyster Mushroom”)

The genus *Pleurotus* was defined by Paul Kummer in 1871. *Pleurotus* species are considered saprophytes, and frequently grow on dead wood and decaying trees (Raman *et al.*, 2021). Unlike many of the well-studied WRFs, several *Pleurotus* species are edible and commercially cultivated in large-scale facilities. *Pleurotus* spp.’s production is significant for the food industry (Deepalakshmi and Mirunalini, 2014), comprising around 25% of cultivated mushrooms worldwide. Some *Pleurotus* species are known for their medicinal properties. *Pleurotus* are grown on a variety of lignocellulosic substrates available locally, such as a wide array of forest and agricultural byproducts (Cohen *et al.*, 2002; Raman *et al.*, 2021).

Degradation of Major Groups of Organic Pollutants

Polychlorinated Biphenyls (PCBs)

Polychlorinated biphenyls (PCBs) are a group of chlorinated aromatic compounds that are considered one of the most toxic and persistent organic pollutants. Their properties include longevity and heat absorbance, and they form an oily liquid at room temperature that is useful for electrical utilities and in other industrial applications. In the 1960s, the toxic effects from exposure to PCB began to be apparent (Alharbi *et al.*, 2018). Consequently, the production and use of these compounds is banned or strictly controlled in many countries, which bans and restrictions were adopted internationally under the Stockholm Convention on Persistent Organic Pollutants (Hung *et al.*, 2016).

The degradation of various PCBs by several WRFs has been reported over the years, including *P. chrysosporium* (Eaton, 1985), *T. versicolor* (Cloete and Celliers, 1999), *P. ostreatus* (Chun *et al.*, 2019), *P. sajor-caju* (Sadañoski *et al.*, 2019), and *Irpex lacteus* (Stella *et al.*, 2016). WRFs were reported to have degraded and treated soil and wood from a disused sawmill area contaminated for decades with chlorinated phenols, dibenzo-p-dioxins, and furans (Valentín *et al.*, 2013).

A technical mixture of PCBs’ degradation pathway was studied by following the metabolites produced by *P. ostreatus*, wherein 41 PCB degradation products were detected and profiled. Accordingly, it was concluded that both intracellular enzymes (cytochrome P-450 monooxygenase, aryl-alcohol dehydrogenase, and aryl-aldehyde dehydrogenase) and the extracellular ligninolytic systems participate in the process (Čvančarová *et al.*, 2012). *P. pulmonarius*’s proteome was studied in the presence of transformer oil containing a mixture of Aroclors 1242, 1254, and 1260 (Sebastian *et al.*, 2021). A total of 705 proteins were identified, of which 111 were only found in the PCBs exposed fungus, and 390 were only found in the absence of PCBs. Upregulation was found for glyceraldehyde-3-phosphate dehydrogenase and transcription factor as well as reductases and oxidases such as laccases and versatile peroxidases; on the other hand, proteins related to carbohydrate and proteolytic metabolism were repressed, suggesting that the fungus faced oxidative stress during the degradation process (Sebastian *et al.*, 2021).

Possibilities and advances in the remediation of PCBs have been reviewed (Chun *et al.*, 2019; Italy *et al.*, 2020). An interesting, likely cost-effective approach was the use of *P. ostreatus* spent substrate in a trickle-bed bioreactor (Šrédlová *et al.*, 2020). This pilot-scale

bioreactor (working volume 500 L) was able to remove to various levels di-, tri-, tetra-, and pentachlorinated PCB congeners. Overall, this experiment proved the suitability of spent oyster mushroom substrate's use in degradation and detoxification of recalcitrant PCBs under non-sterile conditions, even in the presence of bacterial and fungal contaminations.

Polycyclic Aromatic Hydrocarbons (PAHs)

Polycyclic aromatic hydrocarbons (PAHs) are a large group of organic compounds comprised of two or more fused aromatic rings originated mostly from anthropogenic activities resulting in inadequate combustion of materials such as coal, oil, or wood. They pose a serious concern, as they are resistant to biodegradation, bioaccumulate, and may be mutagenic, carcinogenic, teratogenic, and immunotoxicogenic to many organisms, including humans. In addition, these compounds are widely distributed in the environment (Patel *et al.*, 2020). Several approaches for remediation of PAHs have been proposed, including the use of various bacteria and fungi (Cerniglia, 1992; Gramss *et al.*, 1999; Bamforth and Singleton, 2005; Kuppusamy *et al.*, 2017).

PAHs' degradation by WRF was reviewed by Kadri *et al.* (2017), who described culture conditions, kinetics, degradation pathways, and the enzymatic degradation mechanisms. Bumpus *et al.* (1985) was the first to suggest the potential of PAHs bioremediation by *P. chrysosporium*. They demonstrated that the fungus partly mineralized benzo[a]pyrene and phenanthrene (Bumpus, 1989) to carbon dioxide. Hence, *P. chrysosporium* has been the focus of many studies on PAHs degradation under ligninolytic, nutrient-rich, and other culture conditions by ligninolytic extracellular as well as intracellular enzymes (Hammel *et al.*, 1986; Syed and Yadav, 2012; Gu *et al.*, 2016; Bhattacharya *et al.*, 2013; Bogan and Lamar, 1996). *P. ostreatus* metabolized a wide variety of PAHs with little correlation between PAH degradation and extracellular laccases, manganese peroxidases, or manganese-independent peroxidases activities (Bezalel *et al.*, 1996). *Ganoderma lucidum* and *Trametes polyzona*, among other WRFs, were also able to remove various PAHs (Teerapatsakul *et al.*, 2014; Torres-Farrad *et al.*, 2017; Agrawal *et al.*, 2018; Torres-Farrad *et al.*, 2019).

Bezalel *et al.* (1996) demonstrated that *P. ostreatus* is able to metabolize phenanthrene to phenanthrene trans-9, 10-dihydrodiol, and 2,2'-diphenic acid, as well as partially mineralizing it to CO₂. The formation of phenanthrene trans-9R,10R-dihydrodiol, wherein only one atom of oxygen originates from molecular oxygen, suggests that *P. ostreatus* initially oxidizes phenanthrene via a cytochrome P-450 monooxygenase and an epoxide hydrolase (Bezalel *et al.*, 1997). While Park *et al.* (2019) showed that *Dentipellis* sp. KUC8613 was capable of removing PAHs without upregulating ligninolytic genes, out of 154 identified P450 genes in the *Dentipellis* genome, transcription of 15 genes was induced by one or more PAHs. They also found that 1922 genes were upregulated during four PAH removal processes, many of which involving unknown molecular functions. They suggested a pathway that includes initial ring oxidation and a transformation step by glycosyltransferase and glutathione S-transferase, as well as transporters for the translocation of PAHs and their metabolites, lipases for the enhanced solubility of PAHs, and antioxidant enzymes for reduced oxidative stress. This is consistent with Bezalel *et al.* (1997) findings based on metabolite analyzes and physiological and biochemical experiments. Genomic and transcriptomic approaches are suggested as the focus for the next decade of research (Park and Choi, 2020).

Textile Dyes

The textile industry is one of the main contributors to pollution via discharge of untreated effluents containing biologically stable dyes into water bodies. Approximately 15% of dyes utilized during various dyeing processes in various industries, pollute water bodies, threaten our aquatic ecosystems, and may affect human health (Vikrant *et al.*, 2018; Lellis *et al.*, 2019; Tkaczyk *et al.*, 2020). Due to the emerging pollution caused by textile dyes during recent decades, microbial degradation became an option for remediation (Chaurasia and Bharati, 2019; Ihsanullah *et al.*, 2020; Varjani *et al.*, 2020), including the study of several WRFs and their enzymes (Heinfling *et al.*, 1998; Wesenberg *et al.*, 2003; Vikrant *et al.*, 2018; Kalia and Singh, 2020). Eichlerov and Baldrian (2020) studied the decolorization of Orange G and Remazol Brilliant Blue R by 150 saprophytes belonging to 77 *Basidiomycetes* of various ecotypes, WRF, brown rots, and litter decomposers. WRFs were the most efficient at decolorizing both dyes.

Besides being studied for their remediation, textile dyes can also serve as an interesting tool for WRF research, due to the dual role that they play in the study of ligninolytic fungi and their oxidative systems. On one hand, dyes are targets for bioremediation, as aforementioned. On the other hand, they can be used not only as a screening tool, but also as a means of elucidating catalytic mechanisms of biodegradation. The use of dyes as research tools offers a number of advantages, as they are chemically stable, soluble, and inexpensive; and have high molar absorption coefficients. Decolorization of dyes can be tracked in simple, quick, and quantitative spectrophotometric measurements, thereby serving as a basis for easy and accurate phenotypic-based assays for WRFs' efficiency and their ligninolytic system's functionality (Glenn and Gold, 1983; Platt *et al.*, 1985; Salame *et al.*, 2010). For example, the ability to follow azo-dye Orange II decolorization was exploited for screening of RNAi silenced mutants of *P. ostreatus* (Salame *et al.*, 2010). Knockdown of *mnp3*, using RNAi silencing, resulted in the reduction of Orange II decolorization, which was consistent with marked reduction of both *mnp3* and *mnp9* genes' expression levels. Knop *et al.* (2014, 2016) used the azo dyes Orange II and Reactive Black 5 to study versatile peroxidase 1 (VP1) reaction mechanism and also to verify its role in vivo by growing *P. ostreatus* wild type under Mn-deficient conditions, as well as showing that $\Delta vp1$'s knockdown mutant had negligible decolorization capability.

Lucas *et al.* (2008) screened more than 325 WRFs belonging to 76 genera for their ability to decolorize five azo and two anthraquinone dyes. More recently, screening was employed to study a large population of *Schizophyllum commune*'s genetic and physiological diversity and dye-decolorizing spectrum (Choi *et al.*, 2020). They identified 5 excellent strains that strongly decolorized Crystal Violet, Congo Red, and Methylene Blue.

These type of studies can identify the most efficient strains for practical applications and also provide data on their physiology required for designing environmentally friendly processes (Sekan *et al.*, 2019; Kalia and Singh, 2020).

Pharmaceuticals and Personal Care Products

Pharmaceuticals and personal care products may retain their bioactivity in the environment, either as the original molecule or as transformation products. These compounds can be found in trace concentrations planet-wide in freshwater bodies and soils (Kondor *et al.*, 2020; Yadav *et al.*, 2021). The sources of the pharmaceuticals in the environment could be effluents from hospitals, animal husbandry, as well as wastewater treatment plants, as some of these compounds are stable and are not removed during the sewage purification process or even after incubation in treated wastewater-irrigated soil (Fu *et al.*, 2019; Grossberger *et al.*, 2014). Such compounds can find their way back to humans through the food chain (Paltiel *et al.*, 2016).

Degradation of several of the most recalcitrant pharmaceutical compounds by WRFs has been reported, as they have been recognized as an emerging environmental problem and potential risk. Much attention has been given to carbamazepine (CBZ) modification by various white-rot fungi such as *T. versicolor* (Kang *et al.*, 2008; Rodriguez-Rodriguez *et al.*, 2010) and *P. ostreatus* strains F6, N001 (dikaryons) and PC9 (monokaryon) (Golan-Rozen *et al.*, 2011). In a follow-up study, Golan-Rozen *et al.* (2015) followed CBZ's transformation pathways and identified in liquid culture 10,11-epoxy carbamazepine and 10,11-dihydroxy carbamazepine as a dead-end product. However, in solid-state culture based on lignocellulosic substrate, an additional 22 transformation products have been identified. While Lamotrigine (LTG), another persistence drug, was also removed by *P. ostreatus* (Chefetz *et al.*, 2019), most identified transformation products were conjugates of the original compound. *T. versicolor* was able to remove several other pharmaceuticals such as diclofenac, naproxen, and ketoprofen (Marco-Urrea *et al.*, 2010). *P. ostreatus* metabolized clomipramine, mianserin, paroxetine, and sertraline (Kózka *et al.*, 2020). WRF enzymes could also effectively remove diclofenac, antibacterial compounds such as tetracycline oxytetracycline, and triclosan, (Wen *et al.*, 2009; Inoue *et al.*, 2010; Zhang and Geissen, 2010; Maadani Mallak *et al.*, 2020), as well as various cytotoxic anticancer drugs (Yadav *et al.*, 2021). Sulfonamides' biodegradation mechanisms via *P. chrysosporium* have been studied at the transcriptomic level (Zhang *et al.*, 2021).

Degradation of pharmaceuticals in pure culture is only a first step in designing a practical degradation process. Thus, it was important to develop WRF-based reactors that work under more realistic conditions. CBZ was removed when *P. chrysosporium* was grown on polyether foam under non-sterile conditions (Zhang and Geissen, 2012). In this case, nutrients were added to the culture. In a batch fluidized bed bioreactor, Cruz-Morató *et al.* (2013) demonstrated the complete removal of seven pharmaceuticals in Madrid's municipal wastewater under non-sterile conditions. The same type of reactor was used for pre-treatment of hospital wastewater with *T. versicolor* pellets. It was shown that 46 of the 51 detected compounds were partially or completely removed (Cruz-Morató *et al.*, 2014). An air-pulsed fluidized bed bioreactor was used for the continuous treatment of non-sterile real hospital wastewater by *T. versicolor* (Mir-Tutusa *et al.*, 2019). The team was able to keep the fungus active and predominant throughout the process despite the bacterial contaminations. Suspensions prepared from mushroom substrate colonized by *P. ostreatus* removed several pharmaceuticals, including diclofenac and lamotrigine (Hultberg *et al.*, 2020). In another study, two bioreactor types were used to treat both synthetic and real hospital wastewater by *T. versicolor*: Stirred tank bioreactor was compared to trickle-bed bioreactor, based on rice husks, which was found to be more efficient at the task (Tormo-Budowski *et al.*, 2021). The topic of real wastewater treatment systems for the removal of various micropollutants, including pharmaceuticals, was reviewed in detail by Mir-Tutusa *et al.* (2018), who analyzed the advantages, difficulties, challenges, and possible solutions for developing an industrial-scale operation.

Can the Knowledge Accumulated on Biodegradation Lead to Mycoremediation?

Despite the need, interest, and vast research invested in the role of fungi in removing organic pollutants from contaminated environments, to our knowledge, no full-scale WRF-based commercial operation for removal of micropollutants from wastewaters or effluents, as well as terrestrial ecosystems, has been reported thus far.

Many authors have deliberated the advantages and future, but also limitations and bottlenecks, for WRF's application in mycoremediation (Pointing, 2001; Harms *et al.*, 2011; Kulshreshtha *et al.*, 2014; Tortella *et al.*, 2015; Mir-Tutusa *et al.*, 2018; Chun *et al.*, 2019; Ferreira *et al.*, 2020; Akhtar and Mannan, 2020), some of whose arguments are summarized here:

- (1) Mir-Tutusa *et al.* (2018) described several continuous WRF operations at various scales and times of operation, treating a gamut of micropollutants. They concluded that WRF-based reactors could be an efficient technology for removing micropollutants from specific wastewater streams (Mir-Tutusa *et al.*, 2018).
- (2) Treu and Falandysz (2017) demonstrated the need for more studies under local field conditions with indigenous species. They contended that results from specific sites and species may not be applicable for other locations with differing soil types, climates, ecologies, and indigenous microbiomes.

- (3) WRFs' ecology and their constraints and advantages for soil bioremediation were analyzed by Baldrian (2008), who cited the requirement for vigorous fungal inoculum applied with nutrient supplement as a food base. For example, *P. ostreatus* colonizing the spent mushroom substrate (Chung et al., 2019) and *P. chrysosporium* colonizing wood chips (Lamar, 1990) or alginate-immobilized spore suspensions (Lestan and Lamar, 1996).
- (4) A major bottleneck, not often discussed, is the long time required by WRF-based processes. Strain improvement, genetic modification, or search for new species appears to be a challenge. Construction of synthetic microbial communities could be useful (Sharma and Shukla, 2020). In addition, employing means for controlling mycelium morphology, optimizing nutrient supplementation, and designing improved reactors for scaled-up ex situ processes of contamination removal from water and effluents, are of importance.
- (5) Micropollutants are typically found at trace concentrations. Affordable and accurate technologies and instrumentation for micropollutants' extraction and detection and their transformation products at environmental levels should be further developed. This is important not only for the evaluation of the mother compound fate and potential residual toxicity, but also to elucidate degradation pathways.
- (6) Transcriptomic and proteomics information is available for WRF, but mostly from studies related to lignocellulosic biomass degradation (Vanden Wymelenberg et al., 2009, 2010; Alfaro et al., 2016 and, 2020; Fernández-Fueyo et al., 2016; Rytioja et al., 2017; Zhang and Yamaura, 2020; Wu et al., 2021) or as a response to lignin-related mixtures of aromatic compounds resembling some pollutants (Daly et al., 2020). While only a few omics studies have been conducted thus far in relation to elucidation of pollutant degradation by WRFs' mechanisms, they hold potential for better and deeper understanding of WRF bioremediation processes, and will likely be more common in the near future. Moreover, omics studies will probably assist in discovering new gene functions, so far annotated as "unknown", and gene regulation. Metagenomics is useful for studying mycoremediation at the community level to learn about interactions with other microorganisms under non-sterile environments (Wang et al., 2017; Park and Choi, 2020).
- (7) While employing relatively new approaches, such as synthetic biology, systems biology, and metabolic engineering, for bioremediation (Dangi et al., 2019; Jaiswal and Shukla, 2020; Sharma and Shukla, 2020; Zaccaria et al., 2020; Asemoloye et al., 2021) has also been suggested, most data accumulated so far concern bacteria and yeast, and relatively little related to WRFs and their enzymes (Park et al., 2019; Zhang et al., 2021).

In summary, a question that arises in much of the literature reviewed here is: Can the massive knowledge accumulated thus far on the chemistry, biochemistry, physiology, ecology, genomics, and genetics; as well as engineering aspects of aromatic organic pollutant biodegradation by fungi in general and by WRF in particular, be translated into and lead to large-scale, cost-effective, commercial mycoremediation processes? The responses range from skepticism to enthusiasm.

Fungal Chitin and Chitosan

Mostafa M Abo Elsoud, National Research Centre, Giza, Egypt

Introduction

Around the world, the annual synthetic polymers production is approximately 140×10^6 tons. However, these synthetic polymers are somewhat stable and their biodegradation is limited. This necessitates the need for replacement of the synthetic with biodegradable polymers that are compatible with the ecosystem. Among the biodegradable polymers, chitin and chitosan have attracted the attention of the workers in both scientific and industrial field due to their numerous potential applications in biomedicine, agriculture, paper making, food industry, and textile industry (Akila, 2014). The wider applications of chitin and chitosan are not only due to their abundance but also due to their non-toxicity and biodegradability (Islam *et al.*, 2017).

Chitin is the second abundant biopolymer after cellulose with annual biosynthesis of about 100 billion tons (Tharanathan and Kittur, 2003). Chitin is found in exoskeletons of insects and mollusks and also a main component in the shell wastes of crustaceans and in the cell walls of some fungi (Bhuiyan *et al.*, 2013; Yeul and Rayalu, 2013).

Historically, was first isolated by Braconnot (1811) from the cell walls of some types of fungi, i.e., *Agaricus volvaceus*, *Agaricus acris*, *Agaricus cantarellus*, *Agaricus piperatus*, *Hydnum repandum*, *Hydnum hybridum*, and *Boletus viscidus*, where it was named “fungine.” In 1823, fungine was renamed as chitin by Odier (1823), who succeeded in production and isolation of chitin and chitosan from the cuticle of insects almost three decades before the isolation of cellulose (Knorr, 1984). Chitosan was first discovered in 1859 by Rouget (Novak *et al.*, 2003). After its discovery to present, it has become a source of numerous studies due to its versatile biological, chemical, and physical properties and wide range of applications (Bhuiyan *et al.*, 2013). Although it has been found in some types of fungi, chitosan is, mostly, obtained from chitin deacetylation.

Initially, chitin and chitosan were obtained from the shell wastes of shrimps and crabs. However, their discovery in the fungal cell walls opened up the horizon for more research and biotechnological applications due to the absence of allergenic substances and less waste production (Chien *et al.*, 2016). Moreover, fungal chitin and chitosan would offer non-seasonable and stable sources of raw material and consistent characters of the product.

Fungal Cell Wall

The fungal cell wall is a dynamic structure surrounds the fungal cell structures and composed of glycoproteins and polysaccharides. It can be tough, flexible or rigid (Peberdy, 1990; Rouiz-Herrera, 1992). It is essential for cell viability and pathogenesis. It, also, determines the shape of the cell, protects it from osmotic pressure, environmental stress and mechanical injury and acts as a filtering mechanism (Latgé and Calderone, 2002). The fungal cell wall is much more than the outer layer of the fungus; its composition greatly influences the ecology of the fungus and can change in response to environmental conditions and imposed stresses (Latgé, 2010).

Physiological Function of Fungal Chitin and Chitosan

Generally, the fungal cell walls are composed of chitin, chitosan, neutral polysaccharides, and glycoproteins in addition to minor amounts of polyuronides, galactosamine polymers, lipids, and melanin (Wu *et al.*, 2004). Chitin exists in the spores and hyphal cell walls in conjunction with glucan molecules forming microfibrils. These microfibrils are embedded in an amorphous matrix to provide the framework and cell wall morphology and rigidity. Chitosan is not considered as native to animal sources; meanwhile, it presents in some fungal species such as *Mucor*, *Absidia*, and *Rhizopus* as one of the structural components in their cell wall (Rouiz-Herrera, 1992). Chitin and chitosan are thought to increase the cell wall integrity and strength and provide protection against foreign materials, e.g., cell inhibitors and higher temperatures to which fungal cells may be subjected (Adams, 2004; Banks *et al.*, 2005; Baker *et al.*, 2007). Chitin and chitosan represented other functions as revealed by mutants bearing a defect in the complex machinery of chitin biosynthesis, deposition of the polysaccharide in cell walls, or intracellular trafficking of chitin synthases (Specht *et al.*, 1996).

Fungal Cell Wall Composition and Architecture

The fungal cell wall is essential for its survival. The cell wall composition is unique to each fungus, and therefore it forms an ideal target for the development of novel antifungal drugs (Tryphon *et al.*, 2016). Most of the fungal cell walls consist of five major components: β -(1,6) glucan, (1,3) β -glucan, α -(1,3) glucan, glycoproteins, and chitin (un-branched chains of β -(1,4)-linked-N-Acetylglucosamine) (Fig. 1). True fungi do not have cellulose in their cell walls (Webster and Weber, 2007).

Fig. 1 Structural formula and differences between chitin, chitosan and cellulose.

The fungal cell walls are all organized in a somewhat similar way. The structure of the wall, directly, affects wall function and interactions with the environment (Gow *et al.*, 2017). These interactions include immune recognition by animals and plants. Most cell walls are layered. The innermost layer comprises a relatively conserved structural skeletal layer, whereas the outer layers are more heterogeneous and tailored to adopt to the physiological conditions of fungi. The inner cell wall, in most fungal species, consists of a core of covalently attached branched β -(1, 3) glucan with 3%–4% interchain and chitin (Fleet, 1991; Latgé, 2007). Hydrogen bonds are formed between β -(1, 3) glucan and chitin and can be assembled into microfibrils to form a basket-like scaffold around the cell membrane. These branched β -(1,3): β -(1,6) glucans are getting bound to other components i.e., proteins and/or other polysaccharides, which their type and/or amount may vary with the fungal species.

The outer layers of fungal cell wall vary much more than the inner skeletal layer. In the yeasts cells of *Candida* and *Saccharomyces* species and the human pathogen *Pneumocystis jiroveci*, the outer cell wall comprising highly mannosylated glycoproteins that covers the inner wall. In *Aspergillus* and many human pathogens, α -(1, 3) glucan plays a prominent role in the organization of the cell wall, but is absent from the *Candida* and *Saccharomyces* cell walls. The presence of α -(1,3) glucan prevents dectin-1-mediated immune recognition of the underlying β -(1,3) glucan by immune cells (Rappleye *et al.*, 2007). The chemical composition of the cell wall of some fungal phyla is represented in (Table 1).

The cell wall of the yeast *Cryptococcus* is enveloped by a gelatinous capsule composed mainly of glucuronoxylomannan and galactoxylomannan which are attached to the cell wall via α -(1,3) glucan. Worth mentioning, the capsular polysaccharides are synthesized intracellularly and then secreted via exocytosis through the cell wall (Yoneda and Doering, 2006).

The structure and biosynthesis of the budding yeast *S. cerevisiae* cell wall has well been studied. It has been used as model organism to study cell division and cell morphogenesis in eukaryotic cells (Botstein *et al.*, 1997; Hayles and Nurse, 2001). It is, mainly, composed of β -(1,3) glucan, that forms an alkali-soluble fraction or a chitin-linked, alkali-insoluble fraction. Furthermore, it contains β -(1,6) glucan, chitin, and mannoproteins (Klis *et al.*, 1997). *S. cerevisiae* lacks α -glucans. Electron microscopy examination of *S. cerevisiae* showed that the cell-wall is organized in a layered structure where β -(1,3) glucan forms densely interwoven microfibrils present as the innermost layer, followed by β -(1,6) glucan and mannoproteins (Osumi, 1998; Cabib *et al.*, 1982). Most chitin is found in the region of the bud scars which remain after the cell separation, whereas the remainder of the chitin is dispersed over the lateral walls. Similar, with some modifications, layered cell-wall architecture was found in other fungi such as fission yeast *S. pombe* (Kopecká *et al.*, 1995), *C. albicans* (Chaffin *et al.*, 1998), and *A. fumigatus* (Fontaine *et al.*, 2000).

Biosynthesis of Cell Wall Polysaccharides

Polysaccharides of the fungal cell wall such as chitin and glucans are synthesized, in an inactive form, at the plasma membrane of the cell by transmembrane enzymatic complexes via secretory vesicles and then activated after insertion into the plasma membrane (Gow *et al.*, 2017). In contrast to mannans and other glycoconjugates, where they are synthesized in the endoplasmic reticulum and Golgi apparatus then may be conjugated to cell wall proteins, and brought to the cell wall by the classical secretory route via secretory vesicles (Gow *et al.*, 2017). All synthases enzymes use nucleotide diphosphate-sugars as substrates for polysaccharide synthesis, so enzymes of the metabolic pathways responsible for the synthesis of nucleotide sugars are rate-limiting and essential for the construction of the cell wall (Gow *et al.*, 2017).

Table 1 The chemical composition of the cell walls of some fungal phyla (in % dry weight of total cell wall fraction)

Phylum	Example	Chitin	Cellulose	Glucans	Protein	Lipid
<i>Oomycota</i>	Phytophthora	0	25	65	4	2
<i>Chytridiomycota</i>	Allomyces	58	0	16	10	?
<i>Zygomycota</i>	Mucor	9 ^a	0	44	6	8
<i>Ascomycota</i>	Saccharomyces	1	0	60	1	8
	Fusarium	39	0	29	7	6
<i>Basidiomycota</i>	Schizophyllum	5	0	81	2	?
	Coprinus	33	0	50	10	?

^aMainly chitosan.

Chitin Synthases and Synthesis

Chitin, a natural mucobiopolymer, is a hard, white, inelastic, and nitrogenous compound, composed of randomly distributed N-acetyl-D-glucosamine (N-GlcNAc) monomers (Islam *et al.*, 2017). Following cellulose, chitin is considered as the second most abundant biopolymer on earth, with annual biosynthesis of more than 100 billion tons (Tharanathan and Kittur, 2003). In nature, chitin polysaccharide is, enzymatically, synthesized by the transfer of a glycosyl of N-GlcNAc from uridinediphosphate-N-acetyl-D-glucosamine to chitodextrin acceptor (Sitanggang *et al.*, 2012). Chitin is the most ancestral structural polysaccharide in the fungal cell wall (up to 60%) and composed of linear chains of β -(1,4) N-acetylglucosamine (Bartnicki-Garcia, 1968). In *Saccharomyces cerevisiae*, chitin represents about 2% (w/w) of the total cell wall and mainly present at the bud scars (Klis *et al.*, 2002). Wessels (1997) suggested that hyphal growth occurs as the result of a continuously replenished supply of soft wall material at the apex, but there is good evidence that the softness of the apical cell wall is also influenced by the activity of wall-lytic enzymes such as chitinases or glucanases (Fontaine *et al.*, 1997; Horsch *et al.*, 1997). The formation of chitin is very similar to cellulose, which is consistent with their role as a structural polysaccharide (Chandrasekaran, 1997). For chitin, the chemical structure is similar to that of cellulose, which consists of a polymer of several hundred units of β -(1-4) linked D-glucose (Bhuiyan *et al.*, 2014). In chitin, the hydroxyl group at position C-2 of cellulose has been replaced by an acetamide group (Fig. 1).

Unlike cellulose, the nitrogen content of chitin and chitosan is 5%–8% which makes them suitable for typical amines reactions (Kurita, 2001). The synthesis of chitin is mediated by specialized organelles termed chitosomes (Bartnicki-Garcia *et al.*, 1979; Sentandreu *et al.*, 1994) in which inactive chitin synthases are delivered to the apical plasma membrane and become activated upon contact with the lipid bilayer (Montgomery and Gooday, 1985). The major synthases that are responsible for chitin production reside in the cell plasma membrane and utilize UDP-N-acetylglucosamine as the substrate for the chitin formation that is extruded into the cell wall (Fig. 2(A)). In the cell wall, the polysaccharides can be crosslinked or branched together through hydrogen-bonds by the enzymes that reside in the cell wall (Fig. 2(B, C)).

The biochemical functions of many chitin synthases are not exactly known (Bowen *et al.*, 1992; Munro and Gow, 2001; Cabib *et al.*, 2001; Roncero, 2002). Some chitin synthase isoforms may have redundant functions. Although, a homopolymer with only one linkage is the product of all chitin synthase enzymes, these enzymes can synthesize chitin fibrils of differing architecture due to the differences in folding degree and intra-chitin hydrogen bonding of the primary chain (Lenardon *et al.*, 2007).

The families of chitin synthases have been identified bioinformatically, and have molecular weights of 100–130 kDa (Garcia-Rubio *et al.*, 2020). Two families of fungal chitin synthases (Fig. 3) have been identified based on amino acid sequence (Morozov and Likhoshway, 2016).

The role of each of the seven chitin synthase classes is not well understood. The four chitin synthase classes (III, V, VI, VII) are specific to filamentous fungi (Bowen *et al.*, 1992; Fernandes *et al.*, 2016).

Some genes, named CHS, are not associated with the activity of chitin synthase but are involved in its regulation and/or localization. Some chitin synthases are zymogens that become active only after proteolysis and some others are regulated by phosphorylation (Schorr *et al.*, 2001; Valdivia and Schekman, 2003). Some fungi have more than 20 CHS genes, and some have only one (Lenardon *et al.*, 2010).

The chitin synthases (class V and class VII) in filamentous fungi have unconventional myosin motor-like domains (MMD) (Steinberg, 2011). These enzymes are essential for morphogenesis, growth, virulence and stress tolerance. The presence of myosin motor-like domains (MMD) is not required for the motility of some fungal species, e.g., *Ustilago maydis* and *Aspergillus nidulans* (Treitschke *et al.*, 2010). However, its presence may function in tethering vesicles in the apical dome by increasing the residence time at that location favoring vesicle fusion with plasma membrane (Schuster *et al.*, 2012).

Biosynthesis of Chitin and Chitosan

Glycogen is the starting material for chitin synthesis. The first step is the catalysis of glycogen by phosphorylase enzyme where glycogen is converted to glucose-1-phosphate. In the presence of phosphomutase, glucose-6-P is formed and further converted to

Fig. 2 Synthesis and remodeling of β -(1,3) glucan. (A) Putative sequential or concomitant events in the synthesis and remodeling of β -(1,3) glucan. (1) Synthesis of linear glucan chains (glucan synthase complex composed of a catalytic [GS], activating [Act], and regulating [Reg] subunits). (2) Hydrolysis of glucans. (3) Branching of β -(1,3) glucan. (4) Elongation of β -(1,3) glucan side chains. (5) Cross-linking with branched β -(1,3) glucan. GPI-anchored transglycosidase or hydrolases (T) bound to the membrane can act on the polysaccharides in the cell wall space. Panel A provides example. (B) An example of GPI-anchored Gel1 protein involved in the elongation of β -(1,3) glucan inside the cell wall space. (C) Crystal structure of the *S. cerevisiae* Gel1 orthologue, Gas2 complex with acceptor and donor oligosaccharides. The enzyme is shown as a ribbon, the glucan binding domain with green strands and orange helices, and the catalytic domain with blue strands and red helices. A gray transparent molecular surface is shown, revealing an elongated groove on the catalytic domain, in which the laminarioligosaccharides (shown as sticks, with yellow carbon atoms) bind. (D) Biochemical organization of a GPI-anchored protein in *A. fumigatus*. The three domains of the GPI anchor are (1) a phosphoethanolamine linker covalently bound to the protein, (2) a mannan-glucosaminemyo-inositol oligosaccharide, and (3) a ceramide tail attaching the GPI anchor to the cell membrane. fructose-6-P by hexokinase. Fructose-6-phosphate is then converted to N-acetyl glucosamine which involves amination (glutamine to glutamic acid) and acetylation (acetyl CoA to CoA). Isomerization step is as follows (phosphate transfer to C6 to C1 catalyzed by a phospho-N-acetyl glucosamine mutase). Further inter-conversion, uridine diphosphate (UDP) N-acetyl glucosamine is formed by utilization of uridine triphosphate (UTP). Finally, chitin is formed from UDP N-acetyl glucosamine in the presence of chitin synthase. Chitin deacetylation results in chitosan. Chitin deacetylation in the cell wall of fungi is catalyzed by the chitin deacetylase enzyme (EC 3.5.1.41) (Batista *et al.*, 2018). Biosynthetic pathway of chitin is graphically represented in Fig. 4.

Physicochemical Properties

Solubility

Because of its insolubility in most solvents, chitin has very few applications. In contrast, chitosan has many applications because it is, readily, soluble in dilute acidic solutions such as formic, acetic, lactic acids and most solvents at pH < 6.0. However, 1% acetic acid at pH 4.0 is the widely used solvent of chitosan (Zamani *et al.*, 2008).

Molecular Weight

Chitin and chitosan are high molecular weight biopolymers that vary with the variation of the source material, preparation and extraction methods. The suitable applications of chitin and chitosan are determined according to their molecular weight, e.g., it has

been reported that chitosan with low molecular weight has greater antimicrobial activity (Amorim *et al.*, 2003; Franco *et al.*, 2004; Tajdini *et al.*, 2010; Moussa *et al.*, 2013; Oliveira *et al.*, 2014).

The molecular weight of chitin is as high as many Daltons. However, due to the use of harsh chemical treatments, the molecular weight of chitosan may range from 100 to 1500 kDa. Chitosan of low molecular weight can be obtained either by chemical or enzymatic methods (Cai *et al.*, 2006). Although, fungal chitin has unknown molecular mass, it has been proposed that *Saccharomyces cerevisiae* synthesizes a uniform chain of GlcNAc containing 120–170 monomer units which may correspond to 24,000–34,500 Da (Valdivieso *et al.*, 1999).

Degree of Deacetylation

The degree of deacetylation (DD) is one of the most important parameters that affect the chemical and physical characteristics, activity as well as the applications of chitin and chitosan (copolymers) (Akila, 2014). It can be defined as the molar fraction of D-glucosamine (GlcN) in chitosan and represented by the following equation:

$$DD = 100 \frac{n\text{GlcN}}{n\text{GlcN} + n\text{GlcNAc}}$$

where (nGlcN) represents the average number of D-glucosamine units and (nGlcNAc) represents the average number of N-acetyl glucosamine units.

For instance, only chitin samples with degree of deacetylation of about 50% are soluble in water, whereas those with lower or higher degree of deacetylation were insoluble (Wu, 2004). Chitosan molecules with high degree of deacetylation (>85%) have strong positive charge in the aqueous solutions with pH < 6 (Sorlier *et al.*, 2001). Different methods have been proposed by scientists for the determination of chitin and chitosan degree of deacetylation. These techniques include the following:

- (1) Infrared spectroscopy (IR) (Brugnerotto *et al.*, 2001; Duarte *et al.*, 2002): Although this technique requires precise calibration, it is the most popular technique because it is very simple and requires minimal sample preparation.
- (2) ¹³C solid-state NMR (Duarte *et al.*, 2001): This technique is not available at most laboratories due to the elevated cost; however, it appears to be the most reliable method and is often used as a reference.
- (3) High-pressure liquid chromatography (HPLC) (Han *et al.*, 2015): This method depends on the hydrolysis of chitin and chitosan and analysis of the produced acetic acid.
- (4) Potentiometric titration (Ke and Chen, 1990).
- (5) Ultraviolet spectrometry (Liu *et al.*, 2006).

Potentiometric titration and ultraviolet spectrometry require dissolved samples and therefore not suitable for chitosan with (DD < 50%) and chitin.

Occurrence and Biological Functions in Nature

Chitin and chitosan are main components in the shells of crustaceans such as crab, shrimp, and lobster, and are also exoskeleton components of insects and mollusks. They compose a main part of the cell wall of many fungi (Yeul and Rayalu, 2013). However, chitin and chitosan are not present in higher plants and higher animals. It has been reported that chitin represents an average of 14% and 21% of the dry weight of crab and shrimp processing wastes, respectively (Ashford *et al.*, 1977), therefore, currently, shrimp and crab shell wastes are the main industrial sources for the large-scale production of chitin and chitosan. Processing of shrimp and crab shell wastes from marine food factories helps recycling and useful use of these wastes in other fields. Crustacean shell wastes are composed of protein, lipids and inorganic salts, in addition to chitin and chitosan, subsequently, the extraction of chitin and chitosan requires stepwise chemical methods (Kim and Rajapakse, 2005).

Chitin is widely distributed in many fungal phyla (division) including: *Ascomycetes*, *Basidiomycetes*, and *Phycomycetes* (Pacheco-Arjona and Ramirez-Prado, 2014). Fungal chitin is a component of the structural membranes and cell walls of stalks, mycelia, and spores. However, chitin is not found in all fungi and may be absent in one species that is closely related to another as the chitin content within fungal species can vary depending on the method of fungal cultivation and fermentation system (Abo Elsoud and El Kady, 2019).

Chitin was reported in *Saccharomyces cerevisiae* as a major component in primary septa between mother and daughter cells (Sbrana *et al.*, 1995).

Industrial Production of Chitin and Chitosan

The crustacean shells annual production has been estimated as 1.2×10^6 tons worldwide (Synowiecki and Al-Khateeb, 2003). As it has, already, mentioned, crab and shrimp shells are the main industrial source for the large-scale production of chitin and chitosan. These crustacean shell wastes contain, in addition to chitin, proteins, inorganic salts, pigments, and lipids as main

Fig. 5 Process of chitin and chitosan production. Reproduced from Kumar, S., Ye, F., Dobretsov, S., Dutta, J., 2019. Review: Chitosan nanocomposite coatings for food, paints, and water treatment applications. *Applied Sciences* 9 (12), 2409. doi:10.3390/app9122409.

Fig. 6 Deacetylation of chitin to chitosan.

structural components. Therefore, chemical extraction of chitin and chitosan should be employed to obtain the pure product. Briefly, the following steps should be performed (Fig. 5):

- (1) Demineralization/decalcification:
The shell wastes are washed, dried, and ground to smaller sizes where minerals such as calcium carbonate are removed with good mixing with dilute hydrochloric acid at ambient temperature.
- (2) Discoloration:
This step aims to remove pigments from the produced chitin.
- (3) Deproteinization:
The pure chitin and chitosan should be deproteinized to remove the protein contamination. The residual materials are treated with dilute aqueous solution of sodium hydroxide to remove proteins, glycoproteins and branched polysaccharides.
- (4) Acid reflux:
For the separation of chitin and chitosan, the treated material is acidified using 2%–10% hydrochloric acid or acetic at 95°C for 3–14 h.
- (5) Deacetylation:
The resulting chitin is treated with 40%–45% sodium hydroxide, for production of chitosan, in the absence of oxygen, at 160°C for 1–3 h in a process called deacetylation in which the acetyl group is removed from chitin molecules (Fig. 6) (Roberts, 1992). Repetition of this process can give a degree of deacetylation (DD) up to 98%, but the complete deacetylation can never be achieved (Mima *et al.*, 1983).

Table 2 Comparison between chitin and chitosan production from fungal and crustacean sources

Basis for comparison	Fungal mycelia	Crustacean sources
Availability	Does not have seasonal or geographic limitations.	Limited by sites of fishing industry and seasons.
Inorganic materials	Low levels	High levels
Extraction process	Simpler	Requires harsh solvents
Cost of waste management	Low	High
Demineralization treatment	Not required	Required
Physico-chemical properties	Consistent	Vary
Induction of the plant immune response	More effective	Less effective

Note: Abo Elsoud, M.M., El Kady, E.M., 2019. Current trends in fungal biosynthesis of chitin and chitosan. Bulletin of the National Research Centre 43, 59. doi:10.1186/s42269-019-0105-y.

The degree of chitin deacetylation depends on the concentration of NaOH, reaction temperature, and time (Kasaai, 2009). However, at least 85% deacetylation should be achieved for a good solubility of chitosan (No and Meyers, 1995). In contrary to crustacean shell wastes, the crude fungal chitin has a lower level of inorganic matters and thus the step of demineralization is not required during the processing (Teng *et al.*, 2001).

Features of Fungal Chitin and Chitosan Production

During the few last years, the industrial production of fungal chitin and chitosan has attracted the attention of scientists and business men due to their significant advantages over the currently applied processes. These advantages are summarized in (Table 2; Knorr *et al.*, 1989; Rane and Hoover, 1993; Teng *et al.*, 2001; Adams, 2004).

In addition to the above-mentioned differences between chitin and chitosan production from fungal mycelia and crustacean sources, it has been reported that the degree of acetylation, molecular weight, and distribution of charged groups in fungal chitin and chitosan are potentially different from that of crustacean source which enhances bioactivity and promotes their functional properties (Wu *et al.*, 2004). However, further researches are required to get the most economical way for obtaining the chitinous material from fungal mycelia due to the relative higher cost of production. The production of chitin and chitosan from fungi has a significant role in lowering the expenses involved in managing fungal-based waste materials in parallel with production of value-added products which may provide a profitable solution to the biotechnological industries (Wu *et al.*, 2005). The worldwide production of the mushroom, *Agaricus bisporus*, results in about 50,000 metric tons/year of useless waste material. On the other hand, the production of citric acid from *Aspergillus niger* results in approximately 80,000 tons/year of mycelial waste materials (Ali *et al.*, 2002). These fungal wastes and others represent a free natural source of chitin and chitosan.

Chitin and Chitosan-Producing Fungi

The cell walls and septa of many fungal species belong to the classes Basidiomycetes, Ascomycetes, Zygomycetes, and Deuteromycetes contain, mainly, chitin to maintain their strength, shape, and integrity of cell structure (Kirk *et al.*, 2008). Chitin is considered as the second most abundant biopolymer in the fungal cell wall. Also, chitosan can be easily recovered from these microorganisms (Synowiecki and Al-Khateeb, 1997; Yokoi *et al.*, 1998). These fungal classes include: *Absidia coerulea*, *Absidia glauca*, *Absidia blakesleeana*, *Aspergillus niger*, *Colletotrichum lindemuthianum*, *Gongronella butleri*, *Lentinus edodes*, *Mucor rouxii*, *Phycomyces blakesleeanus*, *Pleurotus sajocaju*, *Rhizopus oryzae*, and *Trichoderma reesei* which have been investigated for chitin and chitosan production (Hu *et al.*, 1999; Teng *et al.*, 2001; Chatterjee *et al.*, 2005) and suggested as promising alternative sources to crustaceans (Pochanavanich and Suntornsuk, 2002; Nwe *et al.*, 2002; Suntornsuk *et al.*, 2002). The amount of chitin in the fungal cell wall is specific to environmental conditions and age as well as species. The chitin content in the dry fungal cell wall may vary from 2% to 42% in yeast and Euscomycetes, respectively. Chitosan is also one of the structural components in the fungal cell walls which differ depending on fungal taxonomy. Thus, the cell wall in Zygomycetes contains chitosan-glucan complex, while contains chitin-glucan in Euscomycetes, Homobasidiomycetes, and Deuteromycetes (Rouiz-Herrera, 1992).

Among the investigated species, *M. rouxii* of the Zygomycetes class was the most researched and studied since the quantities of chitin and chitosan in its cell wall reached 35% of the dry weight (Wu, 2004). Chitosan has been mostly studied, produced, and characterized in *Absidia* and *Mucor* (Pochanavanich and Suntornsuk, 2002). However, *A. niger* (produced from citric acid industry) and *Agaricus bisporus*, as waste materials, provide a plenty source of raw materials for chitin and chitosan production (Wu, 2004). The chitin content in *Agaricus* cell walls has been reported to be 13.3%–17.3%, 35%, 20%–38%, and 43%. This broad range of chitin concentrations can be attributed to the fact that chitin content varies, significantly, during the mushroom life-cycle as well as during postharvest storage (Wu *et al.*, 2004).

Applications of Chitin and Chitosan

Biological Properties

Chitin and chitosan have many intrinsic characteristics that make them suitable for versatile applications in various fields. These characteristics include biocompatibility, biodegradability, strong antibacterial effect, non-toxicity, and high humidity absorption (Aranaz *et al.*, 2009). Furthermore, other biological properties such as antitumor, analgesic, hemostatic, antitumor, hypocholesterolemic, antimicrobial, and antioxidant properties have also been reported by researchers (Islam *et al.*, 2017).

Most of the chitin and chitosan biological properties are directly related to their physicochemical characteristics. These characteristics include degree of deacetylation, molecular mass, and the amount of moisture content (Aranaz *et al.*, 2009). For example, chitosan-mediated inhibition of fungal and bacterial growth relies on the functional groups and molecular weight of chitosan. Two theories have been proposed for chitosan antimicrobial activity. The first theory relies on molecular weight; the smaller oligomeric chitosan can easily penetrate the cellular membrane and prevents the cell growth by inhibiting RNA transcription (Klaykruayat *et al.*, 2010). The second relies on the polycationic nature of chitosan which changes the cellular permeability and induce the leakage of intracellular components due to interaction with anionic components of the cell membrane leading to cell death (Lim and Hudson, 2004). Moreover, chitosan may disrupt the microbial cell physiological activities by absorbing the electronegative substrate, e.g., proteins, and finally death of cells (Zheng and Zhu, 2003). The distribution of acetyl groups and the length of polymer chain in chitin and chitosan affect their biodegradation kinetics (Zhang and Neau, 2001). It has been reported that chitosan with a high degree of deacetylation (97.5%) has a higher positive charge density compared to the moderate DD (83.7%), thus confers a stronger antibacterial activity (Kong *et al.*, 2010). The chitin poor solubility is the main limiting factor in its utilization. On the other hand, chitosan is considered as a potential biopolymer due to its free amino groups that contribute polycationic, chelating activity, and dispersion forming properties along with its solubility in dilute acetic acid (Akila, 2014). Due to its exceptional versatile biological, chemical, and physical properties, chitosan can be used in a wide variety of applications including industrial, agricultural, medical and pharmaceutical.

Industrial Applications

In industry, chitosan found many applications in various areas including biotechnology, e.g., enzyme immobilization, cosmetics, paper production, textile, semi-permeable membranes, wastewater treatment, and food processing (Bashar and Khan, 2013).

Agricultural Applications

Chitin and chitosan are potent agents that inhibit the growth of bacterial and fungal plant pathogens, consequently, elicit defense reactions in higher plants (Shibuya and Mimami, 2001). In bell pepper fruit pathogen, chitosan has the ability to effectively reduce *Botrytis cinerea* polygalacturonases causing severe cytological damages to the invading hyphae (Glaouth *et al.*, 1997). Chitin was reported to be eco-friendly and safe for controlling the plant parasitic nematodes (Spiegel *et al.*, 1986). Similarly, spraying chitosan or chitin on the surface of cucumber plants before the inoculation with the pathogen *B. cinerea*, the activity of peroxidase and chitosanase increased causing inhibition of *B. cinerea* (Ben-Shalom *et al.*, 2003). Furthermore, a Brazilian patent by Stamford *et al.* (2015) was published describing the successful application of fungal chitosan as a biofertilizer (Batista *et al.*, 2018).

Biomedical and Pharmaceutical Applications

Chitin and chitosan biopolymers are considered as useful non-toxic and biocompatible materials to be used in various medical devices to treat, augment, or replace tissues, organs, or function of the body. Furthermore, chitosan and its derivatives are promising materials for supporting in tissue engineering applications (Islam *et al.*, 2017). Chitosan serves as a potential material for nerve regeneration, wound-healing management products and wound dressing, burn treatment, cancer treatment, artificial kidney membrane, bioartificial liver (BAL), artificial skin, artificial tendon, articular cartilage, drug delivery systems, e.g., carrier in case of vaccine delivery or gene therapy, blood anticoagulation, bone damage, and antimicrobial applications. Moreover, chitosan has antioxidant, antitumor, anti-diabetic, and antiulcer activities. It is provided as dietary supplements, under several proprietary names, in combination with other substances for weight loss (Candlish, 1999). It has been sold to inhibit fat absorption in Japan and Europe as a nonprescription product (Akila, 2014). Glucosamine (GlcN), chitosan hydrolysate, is an amino monosaccharide that has been reported to have the potential to prevent changes in the joint structure in patients with osteoarthritis (Reginster *et al.*, 2001; Richy *et al.*, 2003). Chitin is considered as a promising treatment for umbilical hernia (Islam *et al.*, 2017).

Fermentation Systems of Fungal Chitin and Chitosan

The content of chitin and chitosan within fungal species can vary depending on the method of fungal cultivation and fermentation system. Two types of fermentation systems can be differentiated: solid-state fermentation (SSF) and submerged fermentation

(SmF), both of which can be used for production of chitin and chitosan from fungi. In solid-state fermentation, the microbial growth takes place on moist solid substrates where no free water flowing (Pandey *et al.*, 2000; Gabiatti *et al.*, 2006). On the other hand, submerged fermentation takes place in liquid medium.

Generally, the production of chitin and chitosan in the cell walls of fungal systems are associated with the fungus biomass concentration. Focusing on biomass concentration difference, and subsequently chitin and chitosan concentration, due to the different cultivations technique, it was shown that SSF of the fungus, *Lentinus edodes*, yielded a greater biomass concentration (up to 50 times), after 12 days of incubation, than that of SmF (Crestini *et al.*, 1996).

There are many reports that confirm that SSF is more efficient in fungal biomass production compared with SmF. However, there are some cases in which the biomass production in SmF exceeds that of SSF. Biomass production by *Pleurotus ostreatus* was compared through SSF and SmF in a study by Mazumder *et al.* (2009). The results showed no significant difference between biomass concentrations in both techniques during the initial growth period. However, after 2 days of growth, SmF produced a higher biomass concentration of *P. ostreatus*. From these studies of fermentation systems, it can be concluded that it is difficult to derive a solid comparison between solid-state and submerged fermentations in terms of biomass concentration. In other way, the suitable fermentation system for chitin and chitosan production is specific to species. The main variation in chitin and chitosan productivity arises due to changes in substrate, environmental conditions and medium composition, etc. (Bhargav *et al.*, 2008). The substrate in case of SSF can be homogenous (e.g., polyurethane foam (PUF)) or heterogeneous (e.g., rice bran, wheat straw, soybean, or other agricultural byproducts). The use of homogenous substrate is advantageous as it allows the control of oxygen transfer, feed rate, medium composition, and facilitates the quantification of fungal biomass. On the other hand, the difficulty of fungal biomass measurement is a major hindrance of using SSF or more specifically the heterogeneous substrate (Zhu *et al.*, 1994; Sparringa and Owens, 1999). In brief, the characterization, optimization, and standardization of SSF process is very difficult. The substrate's physical properties, strongly, affect the rate of oxygen and nutrients diffusion, water activity, and consequently metabolic activity. The difficulty of recovering fungal biomass in case of SSF affects the extraction process of chitin and chitosan. These conditions push toward the use of SmF instead of SSF (Sitanggang *et al.*, 2012). The simple step for determination of the fungal biomass in SmF makes this fermentation system preferred for production of chitin and chitosan. However, the higher probability of contamination, if the aseptic conditions are not maintained, the production of much waste water after biomass recovery, and high energy expenditure during the agitation for adequate mixing are the major obstructions in the use of SmF (Sitanggang *et al.*, 2012).

Conclusion

Chitin and chitosan biopolymers exist in the shells of crustaceans, exoskeletons of insects and mollusks, as well as in the cell walls of fungi. Industrially, they are widely produced from the shells of crustaceans and found many applications in many industries, agriculture, and biomedicine. However, due to the inconsistent structure of chitin and chitosan from crustacean origin, the fungal origins represent an ideal alternative, especially, for biomedical and pharmaceutical applications. Chitin and chitosan production from fungal sources relieves the world from a great amount of biological wastes. The quantity and/or quality of chitin and chitosan in the fungal cell wall may change due to environmental and nutritional conditions.

Chitin Synthases in Fungi

Introduction

Chitin is a linear homopolymer of N-acetyl- β -D-glucosamine (GlcNAc) residues linked by β -1,4 glycosidic bond, and it is an essential cell wall component of fungi. The general chitin synthesis pathway is divided into sequential reactions; the final step is catalyzed by chitin synthases (CHS), which are specifically associated with chitin biosynthesis (Dorfmueller *et al.*, 2014). CHSs belong to the Glycosyltransferase Family 2. The chitin synthase reaction occurs in specialized regions of the plasma membrane. Chitin synthase add single GlcNAc units, which are derived from the nucleotide sugar donor UDP-N-acetylglucosamine (UDP-GlcNAc), to the non-reducing end of the extending chain (Orlean and Funai, 2018). The linear polymers of chitin then assemble into microfibrils of varying diameter and length. Chitin is integrated into the cell wall by crosslinking via β -1,4 glycosidic bonds with the fibrillar β -1,3-glucan, which serves as a backbone in fungal cell wall. Chitin also links with glycoproteins and pigments in the cell wall.

Classification of Fungal Chitin Synthases

Fungal CHSs are membrane integrated enzymes with multiple domains responsible for subcellular localization and activation. All CHSs possess the conserved region CON1, which contains the conserved motifs QxxEY, (E/D)Dx, and Q(R/Q)xRW. These three motifs are essential for catalytic activity (Dorfmueller *et al.*, 2014). The CON1 region also exists in CHSs in non-fungi eukaryotes and in the bacterial chitooligosaccharide synthases NodCs. According to their domain structures and phylogeny based on the conserved CON1 region, fungal CHSs are grouped into seven classes: CHSI-VII. CHSI, II and III contain the chitin_synth_1N (PF08407) and CS1 domain (PF01644) followed by the CON1 region. CHSIV has the CS2 (PF03142) and Cyt-b5 domain (PF00173). In addition to the CS2 and Cyt-b5 domain, CHSV and CHSVII also contain the myosin head (PF00063) and DEK-C (PF08766) domain. CHSVI only has a CS2 domain. In Class CHSIV, CHSV, CHSVI and CHSVII, the CON1 region is within the CS2 domain. There are other CHSs that cannot be grouped into any of the seven classes because they are phylogenetically distant from the classified ones though they may have the same domain structure as the members in one of the seven classes (Liu *et al.*, 2017).

Evolution of Fungal Chitin Synthases

The fungal kingdom is the eukaryotic group with the most complex CHS gene family, which is attributed to a complex evolutionary history of this gene family. Fungal CHSs could have three different CON1 region-containing ancestors, which in turn could share an ancestor with bacterial NodC proteins. The ancestor of CHSI, II and III CHSs could be shared by the CHSs from the kingdoms Alveolata and Stramenopiles, whereas Class IV, V and VII CHSs could share an ancestor with the CHSs from the kingdoms Choanoflagellida, Metazoa, Amoebozoa or Stramenopiles. CHSVI could have its own distinct ancestor. Within the fungal kingdom, two major mechanisms are known to drive the evolution of the CHS gene family. One mechanism is gene duplication and gene loss. The second mechanism is domain recombination and domain accretion. Contraction of the CHS gene family is morphology-specific, with significant loss in unicellular fungi such as baker's yeast *Saccharomyces cerevisiae*, whereas family expansion is lineage-specific with obvious expansion in early-diverging fungi. This complex evolutionary history of CHSs results in a diverse CHS distribution in different fungal taxa. The average number of CHSs in the Ascomycota phylum varies greatly among the subphyla; for example, Pezizomycota, Saccharomycotina and Taphrinomycotina fungi have 6.9, 3.9 and 0.6 CHSs per species, respectively. The number of CHSs is relatively invariable in the Basidiomycota phylum, which ranges from 6 to 8 per species in 9 classes in the Basidiomycota fungi, while only the class Malasseziomycetes has 4.5 CHSs per species. CHSVI has been rarely found in the Basidiomycota fungi. Many more CHSs exist in the early-diverging fungi (Glomeromycota, Zygomycota, Blastocladiomycota, Chytridiomycota and Neocallimastigomycota), and they averagely have ~16 CHSs per species, which is almost 3 times greater than the Dikarya fungi (Liu *et al.*, 2017).

Functions of Chitin Synthases

Chitin provides cell rigidity and determines cell shape. It also confers protection against abiotic stresses and is important for full virulence of pathogenic fungi with diverse host ranges (Liu *et al.*, 2017). For example, CHSV and CHSVII are involved in the formation of the infection structure (appressorium) in the insect pathogenic fungus *Metarhizium robertsii*, and in the plant pathogenic fungi *Magnaporthe oryzae*, *Colletotrichum graminicola* and *Fusarium verticillioides*. These two CHSs are also important for

full virulence of the opportunistic human pathogenic fungus *Aspergillus fumigatus*. Chitin synthases are absent in plants and mammals, and are consequently considered as promising targets for antifungal drugs (Ruiz-Herrera and San-Blas, 2003).

Glucose Metabolism and Use of Alternative Carbon Sources in Medically-Important Fungi

Introduction

Nearly 150 million of human populations are affected by potentially life-threatening mycoses worldwide, and millions of them are killed by these fungal infections despite advancement in medical interventions (Bongomin *et al.*, 2017). However, these fungal diseases are as yet a disregarded issue by public health authorities even though most deaths caused by fungal infections are preventable. Although the global species richness of fungi is estimated to be around 1.5–5.1 million, only a hundred of these identified fungi are medically-important and are able to cause serious mycoses in human (O'Brien *et al.*, 2005; Köhler *et al.*, 2015). In contrast to ectothermic vertebrates like insects and plants, endothermic and homeothermic vertebrates such as humans and mammals are generally resistant to fungal infections owing to their evolved antifungal immunity (Robert and Casadevall, 2009; Bergman and Casadevall, 2010). In order to thrive as a successful fungal pathogen in human host, these fungi must be able to grow at human body temperature (37°C and above), breach the host tissue barriers, scavenge and assimilate nutrients from the host tissues and most importantly, also withstand the host immune onslaught (Köhler *et al.*, 2015). Therefore, it is sensible that only a relatively small subset of these identified fungi can cause critical fungal infections in humans.

The growth of fungal pathogens in human host depends primarily on their ability to exploit and assimilate the nutrients efficiently. Although the host niches contain a rich and diverse variety of nutrients, it is still challenging for a fungal pathogen to scavenge for these food resources as the host constantly imposes restriction of the essential nutrients available to the pathogens, a mechanism termed “nutritional immunity” (Rohmer *et al.*, 2011). Therefore, the ability to counteract the limited nutrient condition is particularly crucial for intracellular fungal pathogens. The microenvironments within the host cells often lack of major nutrients (e.g., carbon and nitrogen sources) and trace elements that are readily usable by these pathogens, as most of these nutrients are sequestered in complex forms (Steele *et al.*, 2015). To survive inside the host cells, these fungal pathogens must be equipped with high degree of metabolic flexibility and possess unique metabolic adaptation strategies that are required for effective nutrient acquisition, as pathogenic fungi require high amount of energy for proliferation and dissemination (Ene *et al.*, 2014). Furthermore, it is undeniable that the linkages between nutrients assimilation and fungal pathogenicity as well as their efficacy in combating host defenses are also inextricable (Brown *et al.*, 2014). For instance, multiple fitness and pathogenic attributes of *Candida* species such as biofilm formation, morphogenesis, antifungal resistance as well as immune evasion have been reported to be drastically influenced by the host nutrients, and many of these changes also significantly confer an edge for fungal pathogenicity (Ene *et al.*, 2012, 2013; Brown *et al.*, 2014; Chew *et al.*, 2019a).

All major medically-important fungi such as *Candida* and *Pneumocystis* (exclusively found in warm-blooded mammals), *Aspergillus*, *Cryptococcus* and *Histoplasma* (also found in environment niches) display very distinct lifestyles, and, these differences have exerted evolutionary pressures that shifted or streamlined the fungal metabolic profiles and flexibility (Ene *et al.*, 2014). Carbon sources represent one of the most essential nutrients and the main source of energy required for biosynthesis processes (e.g., biomass generation), and a considerable quantity of these carbon sources are usually needed to sustain the survival of fungal pathogens in the host (Ene *et al.*, 2014; Ramachandra *et al.*, 2014). Similar to most organisms, fungi have preference for certain carbon sources. Glucose is generally the most favorable carbon source for most pathogenic fungi, as metabolism of glucose via glycolysis and respiration are rapid and energetically favorable. However, when the host niches are under glucose deprivation, these fungal pathogens can also utilize a wide range of fermentable sugars and alternative carbon sources, although the mechanisms involved are energetically demanding. Nevertheless, the alternative carbon utilization profiles vary greatly among medically-important fungi, presumably reflect their long-term co-evolution with multiple host niches in human. In the following sections, we review the current knowledge on the glucose and alternative carbon metabolism in fungal pathogens and their importance in the fungal survival and pathogenicity with occasional reference to *Saccharomyces cerevisiae*. Here, we decided to pivot on the metabolism of glucose and alternative carbon sources in major fungal pathogens that are commonly found in human diseases, with the main focus on *Candida*, *Aspergillus* and *Cryptococcus* species.

Glucose Metabolism in Medically-Important Fungi

Glucose is the primary carbon source for most fungi. It is the most preferred source for metabolism in comparison to other carbon sources such as acetate, lactate and fatty acids. Other than metabolism, glucose also plays role in the pathogenicity of many human fungal pathogens. It affects the adhesion property, oxidative stress resistance, biofilm formation, morphogenesis, invasion, and antifungal drug tolerance (Rodaki *et al.*, 2009; Sabina and Brown, 2009; Buu and Chen, 2014; Mandal *et al.*, 2014; Ng *et al.*, 2016; Mikamo *et al.*, 2018; Chew *et al.*, 2019a). Being the most important carbon source, glucose is found in varying concentrations in various host niches and fungi have evolved to adapt to these conditions as they make human as their host. Various organs and host

niches have different concentration of glucose (Ehrström *et al.*, 2006); hence each fungus has evolved to ensure their survivability in these niches such as the mouth, gut, skin, vagina and blood. The median concentration of glucose in the human host hovers around 5.0–5.2 mM in plasma and vagina, respectively (Ehrström *et al.*, 2006). To enable them to utilize glucose, these fungi are equipped with glucose sensors which are found on their cellular plasma membrane.

Most of glucose metabolism mechanisms are discovered mainly through the study of *S. cerevisiae* as the model organism. Glucose metabolism in fungi begins with its acquisition from their surroundings. For this acquisition to take place, fungi develop glucose sensing and transport mechanism. To date, there are three glucose sensing mechanisms which have been identified (Ozcan and Johnston, 1995; Rolland *et al.*, 2000; Thevelein *et al.*, 2000; Kayikci and Nielsen, 2015). The first mechanism involves sugar receptor-repressor (SRR) or hexose transporter (HXT) induction pathway where it involves transporter-like proteins known as Snf3 and Rgt2. The protein orthologues of both the proteins in medically important fungi *Candida albicans* and *Candida glabrata* are Hgt4 and Snf3/Rgt2, respectively. However, for *Cryptococcus neoformans* and *Aspergillus*, attempts so far have not been able to identify them (Liu *et al.*, 2013) except in *Neurospora crassa* where RCO-3 gene was identified (Madi *et al.*, 1997). Besides, Hxs1 and Hxs2 of *C. neoformans* are homologs of Snf3 and Rgt2 in *S. cerevisiae* but both do not act as glucose sensors but as transporters (Liu *et al.*, 2013). The second sensing mechanism is through G-protein coupled receptor Gpr1 and the third involves the glucose repression pathway. All three pathways are interconnected in regulating the level of glucose according to the demand and its availability in the surrounding.

In the SRR pathway, glucose sensors are divided into two groups, namely the high and low affinity glucose sensors. The availability and concentration of glucose influence the activation of these glucose sensors. When glucose concentration is low, the high affinity glucose sensor Snf3 is activated and likewise when glucose concentration is high, the low affinity glucose sensor Rgt2 is activated (Ozcan and Johnston, 1999; Ng *et al.*, 2015). Upon their activation, downstream signals are detected by casein kinase I Yck1/2 which then phosphorylate two transcriptional regulators, Mth1 and Std1 (Moriya and Johnston, 2004). The phosphorylation of both the regulators results in their ubiquitination with Grr1 that ends with their degradation by proteasome (Moriya and Johnston, 2004). Without the presence of Mth1/Std1 coupled Rgt1 complex, the expression of glucose transporters is unimpeded and hence the process of glucose uptake ensues.

In the glucose sensing mechanism by G-protein coupled receptor Gpr1, the presence of glucose results in the activation of adenylate cyclase Cyr1 which increases the level of cAMP levels and activation of protein kinase A (PKA) (Rolland *et al.*, 2000). Coupled together with the presence of sugar-phosphate activation of Cdc25 and Ras, the uptake of glucose takes place. The last mechanism which is known as glucose repression pathway begins with dephosphorylation of Snf1 and Mig1. The dephosphorylation as a result of the presence of glucose enables Mig1 to gain entry in nucleus and acts as a transcriptional repressor of the *GAL* and *MTH1* genes. Activation of both the G-protein coupled receptor and glucose repression pathways consequently leads to the preference of fermentation process over respiration and represses the utilization of alternative carbons for metabolism in *S. cerevisiae*. Following glucose sensing, the glucose sensors genes send signals to glucose transporters. Further in depth reading on all three glucose sensing mechanisms in *S. cerevisiae*, *C. albicans* and *C. glabrata* can be found in a review chapter by Van Ende *et al.* (2019).

Glycolysis is an essential central metabolic pathway that is responsible for catabolism of glucose in order to produce energy and key intermediates for use in the subsequent metabolic pathways (Dashty, 2013). Upon uptake by the cells, glucose enters glycolysis after the first phosphorylation step catalyzed by hexokinases and turns into glucose-6-phosphate. Following a series of enzymatic reactions, catabolism of glucose via this glycolytic pathway ultimately converts this sugar phosphate into the key metabolite pyruvate (Askew *et al.*, 2009). Other than the two pyruvates, two adenosine triphosphate (ATP) and two nicotinamide adenine dinucleotide (NADH) molecules are also generated in the process. At the end of glycolysis, fungi employ two distinct approaches in liberating the remaining energy within pyruvate, i.e., via respiration and fermentation. In general, fungi can be classified as either Crabtree-positive or Crabtree-negative based on their preference in carbon utilization. Crabtree-positive yeasts like *S. cerevisiae* prefer fermentation over cellular respiration even in the presence of oxygen. Fast consumption of glucose and ethanol production are believed to assist Crabtree-positive yeasts to thrive and outcompete other microbes within a polymicrobial ecosystem (Ata *et al.*, 2018). In comparison, Crabtree-negative fungi like *C. albicans* prefer cellular respiration in the presence of glucose (or both respiration and fermentation simultaneously), and generate significantly more energy in the form of ATPs via tricarboxylic cycle (TCA cycle) and oxidative phosphorylation.

Pyruvate oxidation, a decarboxylation process catalyzed by pyruvate dehydrogenase complex, subsequently converts pyruvate molecules into acetyl coenzyme A (acetyl-CoA). Acetyl-CoA is an important fuel for the TCA cycle in cellular respiration for energy production. In comparison to fermentation, cellular respiration generates significantly more energy (18 ATPs per glucose molecule) via oxidative phosphorylation as it can generate additional ATPs from the products of the TCA cycle (mainly NADH and FADH₂) (Askew *et al.*, 2009; Pfeiffer and Morley, 2014). In contrast, the fermentation process does not involve the electron transport chain system, thus no additional ATPs is generated due to lack of oxygen (two ATPs per glucose molecule) (Pfeiffer and Morley, 2014).

Availability of glucose affects the fungi's decision to undergo cellular respiration using glucose or to utilize alternative carbon sources. Generally, *S. cerevisiae* and many other yeast species repress metabolic pathways dedicated for alternative carbon utilization when glucose availability is not a limiting factor (Crabtree-positive), thus suggesting that they prioritize sugar assimilation over other alternative carbon sources (Flores *et al.*, 2000). On the contrary, human fungal pathogen like *C. albicans* simultaneously uses both glucose and other carbon sources even in the presence of glucose (Crabtree-negative). It is perhaps owing to the reasons that *C. albicans* has adapted to not solely dependent on glucose unlike its distant cousins *S. cerevisiae* and *C. glabrata* which all three

share common ancestors 200 million years ago (Dujon, 2005). This is in anticipation that *C. albicans* faces host niche environment that are mostly hostile where glucose level is commonly found to be in low concentration (Sandai et al., 2012).

Multiple studies have shown that key enzymes for alternative carbon utilization in *S. cerevisiae* were subjected to ubiquitin-mediated degradation in the presence of glucose (Schork et al., 1995; Schüle et al., 2000; Horak et al., 2002; Regelmann et al., 2003; Sandai et al., 2012). However, Sandai et al. (2012) have demonstrated that differential evolutionary rewiring of ubiquitination sites in the glyoxylate cycle enzyme isocitrate lyase (Icl1) has bestowed *C. albicans* the ability to retain its key metabolic functions, greatly enhances the fungal metabolic flexibility, and permits concurrent assimilation of glucose and alternative carbon sources. This trait is extremely crucial for a successful fungal pathogen like *C. albicans* as its prime directive involves rapid colonization in various host niches (Sandai et al., 2012). The improved metabolic flexibility in *C. albicans* attributed to the insensitivity to ubiquitin-mediated catabolite inactivation is a virulent determinant. Childers et al. (2016) have reported that *S. cerevisiae* that lack glucose-mediated degradation system (similar to *C. albicans*) were less susceptible to macrophage killing and showed enhanced virulence in murine model, further suggesting the importance of post-transcriptional modification in metabolic flexibility and pathogenesis of medically-important fungi.

Alternative Carbon Metabolism in Medically-Important Fungi

In most conditions, glucose is the preferred carbon source for medically-important fungi, and it is crucial for maximum fungal growth and development. For many microorganisms, glucose is not always available and the only accessible carbon sources are simpler carbon compounds (Lorenz and Fink, 2002). Therefore, when the availability of glucose is scarce, survival of these fungal pathogens depends on the efficient uptake, utilization and metabolism of alternative carbon sources (Ene et al., 2014). Medically-important fungi have been reported to be able to utilize other fermentable sugars (e.g., pentoses and hexoses) and non-fermentable carbon sources, including but not limited to long- and short-chain fatty acids, organic acids, alcohol and amino acids (Lorenz and Fink, 2001; Rude et al., 2002; Hynes et al., 2006; Ramírez and Lorenz, 2007; Turcotte et al., 2010; Chew et al., 2019b). However, most human fungal pathogens have streamlined their carbon utilization profile and prioritize glucose over other carbon sources, mainly because the metabolic processes involving glucose metabolism are energetically favorable (Ene et al., 2014).

In human body, alternative carbon sources can be found in different host niches. Lactate and acetate, two of the most common carboxylates, are commonly produced by the lactic acid bacteria (LAB) in the gastrointestinal and vaginal tract, via breakdown of complex polycarbohydrates (Yamaguchi et al., 2005; Turcotte et al., 2010; Miramón and Lorenz, 2017). While most tissues in human body also produce lactate in excess, highest amount of lactate production usually occurs in the muscle tissue (Andersen et al., 2013). Under normal circumstances, lactate concentration is below 2.0 mmol/L, as approximately 70% of the excessive lactate is rapidly cleared by the liver and also to the lesser extent by the kidneys (Phypers and Pierce, 2006; Andersen et al., 2013). Similarly, low concentration of acetate is generally present in human blood, ranging from 0.05 to 0.2 mmol/L, and subjected to further increase following intake of ethanol (Richards et al., 1976; Tollinger et al., 1979; Pomare et al., 1985; Davies et al., 2011).

Fatty acids are important components that serve many essential roles in human body, and generally can be found as free circulating fatty acids or in esterified forms such as glycolipids, phospholipids and triacylglycerols (Nagy and Tiuca, 2017). The amounts of fatty acids in plasma and human tissue varies considerably in response to various factors, such as differences in gastrointestinal absorption rate, metabolic activity and dietary intake (Risé et al., 2007). Nitrogen sources like amino acids can also be exploited as alternative carbon sources to support fungal growth during glucose-limited condition. In the midst of glucose starvation, endogenous alternative carbon sources can also be generated by fungal pathogens via mobilization of intracellular resources through autophagy. In fact, the ability to subvert nutrient deprivation through recycling of intracellular component is extremely vital for many fungi like *Aspergillus fumigatus*, *C. glabrata* and *C. neoformans* (Richie et al., 2007; Hu et al., 2008; Roetzer et al., 2010; Shimamura et al., 2019). This observation further strengthens the importance of alternative carbon sources in maintaining cellular function and survival of intracellular fungi.

Alternative carbon metabolism is initiated when glucose availability is scarce, and the first step of the metabolism involves efficient uptake of extracellular carbon sources. The modes of transportation are unique to each types of carbon sources, and this has been extensively reviewed (Turcotte et al., 2010; Chew et al., 2019c). Many fungal pathogens including *Candida*, *Aspergillus* and *Cryptococcus* species are able to utilize glycerol as the sole carbon source (Ramírez and Lorenz, 2007; Price et al., 2011; De Assis et al., 2015; Chew et al., 2019b). Glycerol is first converted into glycerol-3-phosphate (G3P) by glycerol kinase (EC 2.7.1.30), subsequently into dihydroxyacetone phosphate (DHAP) by glycerol-3-phosphate dehydrogenase (EC 1.1.1.8), and finally reversibly converted into glyceraldehyde 3-phosphate (GA3P) by triose phosphate isomerase (EC 5.3.1.1). On the other hand, uptake of lactate involves short chain carboxylates transporters such as Jen1 and Jen2 in *S. cerevisiae* and *C. albicans* (Casal et al., 1999; Soares-Silva et al., 2004), Jen4 in *C. neoformans* (Niedźwiecka et al., 2019) and JenB in *Aspergillus nidulans* (Sá-Pessoa et al., 2015). Lactate is ultimately converted to pyruvate by oxidoreductase (EC 1.1.2.3). Both GA3P and pyruvate serve as intermediates to fuel gluconeogenesis for fungal growth in the absence of glucose.

Metabolism of fatty acids in fungal pathogens requires a functional beta-oxidation, and this pathway is essential for the breakdown of fatty acids to obtain acetyl-CoA as an important carbon and energy intermediates. Similarly, acetyl-CoA is also generated from utilization of ethanol and acetate. Ethanol is transported via passive diffusion, whilst acetate is believed to be transported via the acetate uptake transporter (AceTr) family, including Ady2 and Ato1 orthologues in *Candida* species (Casal et al., 2008; Alves et al., 2020), and AcpA in *A. nidulans* (Robellet et al., 2008). Net oxaloacetate derived from acetyl-CoA can be used in

fungi via the glyoxylate cycle to replenish the tricarboxylic acid (TCA) cycle for energy production, or to fuel gluconeogenesis for cellular building blocks generation.

Pathways for Alternative Carbon Metabolism and Their Roles in Fungal Pathogenicity

Beta Oxidation of Fatty Acids

It is undeniable that catabolism of fatty acids via beta-oxidation is imperative for growth and development of many fungi (Hynes *et al.*, 2006). In mammals, beta-oxidation of long-chain fatty acids occurs in peroxisomes, whilst shorter fatty acids are metabolized by the mitochondria (Strijbis and Distel, 2010). Although beta-oxidation of fatty acids is believed to be exclusively peroxisomal in certain fungal species such as *S. cerevisiae*, *C. albicans*, *Yarrowia lipolytica* (Smith *et al.*, 2000; Strijbis and Distel, 2010), multiple studies have suggested that many fungal species harbored both peroxisomal and mitochondrial beta-oxidation pathways (Cornell *et al.*, 2007; Shen and Burger, 2009). In fact, mitochondrial beta-oxidation of fatty acids has been reported in *A. nidulans*, *C. neoformans* and *Candida lusitanae* (Maggio-Hall and Keller, 2004; Kretschmer *et al.*, 2012; Gabriel *et al.*, 2014). Activation of fatty acids generates their corresponding acyl-coenzyme A (CoA), followed by oxidation steps catalyzed by three distinct enzymes, namely acyl-CoA oxidase (EC 1.3.3.6), multifunctional enzyme [enoyl-CoA hydratase (EC 4.2.1.17) and 3-hydroxyacyl-CoA dehydrogenase (EC 1.1.1.35)] and 3-ketoacyl-CoA thiolase (EC 2.3.1.16). At the end of the reactions, acetyl-CoA and an acyl-CoA that is two carbons shorter are generated, with the latter substrate subjected to further beta-oxidation (Hynes *et al.*, 2006; Schulz, 2008; Strijbis and Distel, 2010). Different fungi encode different isoforms of these beta-oxidation enzymes that possess varying affinities toward long-, medium- and short-chain fatty acids. For instance, it has been reported that human fungal pathogen *C. albicans* possess two acyl-CoA oxidases, one multifunctional enzyme and three 3-ketoacyl-CoA thiolase. Interestingly, *C. albicans* has a higher number of enzyme isoforms compared to the baker's yeast, which possess only one acyl-CoA oxidase, one multifunctional enzyme and one 3-ketoacyl-CoA thiolase (Strijbis and Distel, 2010). The increased number of isoforms in *C. albicans* suggests the enhance capability of human fungal pathogen in fatty acids utilization. The resulting acetyl-CoA from catabolism of fatty acids can be further processed by the glyoxylate cycle.

Previous study conducted by Lorenz *et al.* (2004) has demonstrated that almost all enzymes encoding genes in the beta-oxidation pathway (with the exception of genes encode for three isoforms of 3-ketoacyl-CoA thiolase) were significantly up-regulated in *C. albicans* phagocytosed by macrophages, indicating intracellular fatty acids utilization. In addition, genes involved in the beta-oxidation of fatty acids (e.g., *POX1-3*, *PXP2*, *ECN1*, *FOX2*, *FOX3* and *POT1*) were also similarly induced in *C. parapsilosis* and *C. tropicalis* in response to human whole-blood (Kämmer *et al.*, 2020). Disruption of *FOX2* severely reduce the capability of *C. albicans* in metabolism of oleic acid, while complementation of the mutant strain with the wild-type gene fully restored beta-oxidation activity (Piekarska *et al.*, 2006). Moreover, *C. albicans* mutant strain lacks *FOX2* also demonstrated reduced virulence in a murine model of systemic candidiasis (Piekarska *et al.*, 2006; Ramírez and Lorenz, 2007). In *A. nidulans*, deletion of a putative multifunctional enzyme (*foxA*), homolog of *S. cerevisiae* and *C. albicans* *FOX2* responsible for peroxisomal beta-oxidation inhibited growth on very long-chain fatty acids (VLCFAs, C₂₂ and above), severely hampered the growth on long-chain fatty acids (LCFAs, C₁₃-C₂₁), but has no effect on the growth on short-chain fatty acids (SCFAs, C₆ and below) (Maggio-Hall and Keller, 2004). Indeed, *A. nidulans* possess mitochondrial enoyl-CoA hydratase (*echA*), an enzyme involved mitochondrial beta-oxidation of short-chain fatty acids (Maggio-Hall and Keller, 2004). It is reported that disruption of *echA* significantly reduced *A. nidulans* growth on VLCFAs, LCFAs and completely abolished the growth on SCFAs. In *A. fumigatus*, putative genes involved in beta-oxidation such as *mfp* (*foxA*), *echA*, *farb1*, *farb2*, *scdA*, and *aoxA* have been reported to be highly induced in response to human neutrophils, signifying the importance of this pathway in human fungal pathogen (Sugui *et al.*, 2008).

In *C. neoformans*, both peroxisomal (*MFE2*) and mitochondrial (*HAD1* and *HAD2*) beta oxidation have been shown to be highly induced following exposure to fatty acids, and in response to lung pulmonary cryptococcosis in mice (Kretschmer *et al.*, 2012). Defect in *MFE2* and *MFE2* plus *HAD1* (but not *HAD1* alone) significantly attenuated the virulence of *C. neoformans* in a mouse model of cryptococcosis, firmly suggesting that peroxisomal beta-oxidation plays a more prominent role in the pathogenicity of this fungal pathogen, as compared to the mitochondrial pathway (Kretschmer *et al.*, 2012). The same study also showed that a non-functional peroxisomal beta-oxidation also affect the phenotypes of *C. neoformans* at multiple levels, this includes reduction of melanin and capsule formation, increased resistance to cell wall inhibitory and antimycotic agents, and enhanced proteases activity. Ironically, another major human fungal pathogen *Histoplasma capsulatum* does not seem to favor fatty acids utilization in order to propagate within macrophages (Shen *et al.*, 2020). It is reported that *H. capsulatum* is unable to utilize both SCFAs and LCFAs *in vitro*, and down-regulates beta-oxidation pathway in response to macrophage engulfment. Furthermore, disruption of *FOX1* involved in beta-oxidation does not render the strain avirulent, confirming the insignificant role of fatty acid metabolism in pathogenicity of *H. capsulatum* (Shen *et al.*, 2020). Also, beta-oxidation is not found in all three species of *Pneumocystis*, namely *Pneumocystis jirovecii*, *Pneumocystis carinii* and *Pneumocystis murina* (Ma *et al.*, 2016).

The Glyoxylate Cycle

The glyoxylate cycle is a special variant of the tricarboxylic cycle (TCA) that allows utilization of two carbons compounds in the absence of glucose. The glyoxylate cycle is generally not present in human and animal tissue, and can only be found in plants,

bacteria, fungi and protists (Chew *et al.*, 2019c). As a shunt in the TCA cycle, the glyoxylate cycle shares three out of five metabolic enzymes with the cycle: malate dehydrogenase (EC 1.1.1.37), citrate synthase (EC 2.3.3.1) and aconitase (EC 4.2.1.3), by-passing the two decarboxylation steps catalyzed by isocitrate dehydrogenase (EC 1.1.1.41) and α -ketoglutarate dehydrogenase complex (EC 1.2.4.2, EC 2.3.1.61, EC 1.8.1.4) (Kondrashov *et al.*, 2006; Kunze *et al.*, 2006). Instead of converting isocitrate to α -ketoglutarate in TCA cycle, the glyoxylate cycle enzyme isocitrate lyase (EC 4.1.3.1) catalyzes the conversion of isocitrate (C_6) into glyoxylate (C_2) and succinate (C_4). Subsequently, malate synthase (EC 2.3.3.9) catalyzes the condensation of glyoxylate with acetyl-CoA (C_2) to produce malate (C_4) and a free CoA molecule (Chew *et al.*, 2019c). In this way, malate can be further oxidized into oxaloacetate, an important precursor for gluconeogenic biosynthesis of glucose and other sugars. Alternatively, malate that is generated from the alternative carbon utilization (e.g., fatty acids, ethanol and acetate, via acetyl-CoA) also replenishes the energy-producing TCA cycle (Dunn *et al.*, 2009). In short, the glyoxylate cycle intermediate serve as a linkage between anabolic and catabolic fungal metabolism in the midst of glucose deprivation and enables assimilation of alternative carbon sources. As both isocitrate lyase and malate synthase are the exclusive enzymes required for a functional glyoxylate cycle, they are often considered to be the hallmark for this anaplerotic pathway (Kondrashov *et al.*, 2006). These key enzymes of the glyoxylate cycle are also highly conserved among plants, bacteria and fungi (Kondrashov *et al.*, 2006; Dunn *et al.*, 2009). With the only remarkable exception of *S. cerevisiae* cytosolic isocitrate lyase, both key enzymes are generally peroxisomal in fungi (Taylor *et al.*, 1996; Kunze *et al.*, 2006; Hynes, 2010; Strijbis and Distel, 2010).

Both key enzyme genes from the glyoxylate cycle *ICL1* (isocitrate lyase) and *MLS1* (malate synthase) are highly up-regulated in phagocytosed *C. albicans* subjected to human blood (Lorenz and Fink, 2001; Fradin *et al.*, 2003; Lorenz *et al.*, 2004), and *ICL1* is proven to be required for the full virulence of this intracellular pathogen (Lorenz and Fink, 2001; Ramírez and Lorenz, 2007). Similar observation has also been reported in non-*C. albicans* *Candida* (NCAC) species like *C. glabrata*. It has been reported that the glyoxylate cycle is essential for the metabolic flexibility and virulence of *C. glabrata* in a murine model of invasive candidiasis (Chew *et al.*, 2019b). In comparison to *C. glabrata*, loss of *ICL1* engendered much more defects in *C. albicans*, as it also affects the growth on glycerol, in addition to other carbon sources such as ethanol, acetate and fatty acids (Ramírez and Lorenz, 2007; Chew *et al.*, 2019b). In both *Candida* species, the utilization of alternative carbon sources via the glyoxylate cycle also induced multiple physiological changes associated with the pathogenicity of the fungi. For instance, alternative carbon sources greatly influenced the cell wall properties of *C. albicans*, resistance to environmental stresses and antimycotic agents, immune recognition, fitness and virulence of *C. albicans* in vivo (Ene *et al.*, 2012; Ene *et al.*, 2013). For *C. glabrata*, growth on various carbon sources, i.e., glucose, acetate, lactate, ethanol, glycerol and oleic acids altered the fungal cell wall (β -glucan and chitin), biofilm growth and resistance to antifungal and oxidizing agent (Mota *et al.*, 2015; Chew *et al.*, 2019a). Furthermore, assimilation of acetic acid as alternative carbon source also significantly affects the interaction of *C. glabrata* with macrophages (Mota *et al.*, 2015).

In *Aspergillus* species, the homologs of *ICL1* and *MLS1* genes are known as *acuD* and *acuE*, respectively (Ebel *et al.*, 2006; Hynes *et al.*, 2006). In comparison to *Candida* species like *C. albicans* and *C. glabrata*, whereby the glyoxylate shunt is essential; *acuD* and *acuE*, and hence the glyoxylate cycle is not required for the full virulence of *A. fumigatus* (Schöbel *et al.*, 2007; Olivas *et al.*, 2008). Schöbel *et al.* (2007) speculated that *A. fumigatus* does not depend on fatty acids and acetate as one of the major carbon sources for survival and invasive growth, as the *acuD* mutant is still capable of strong hyphal formation. Potentially, *A. fumigatus* could rely on other carbohydrates and proteins during a short period of time upon phagocytosis, and prioritize on aggressive hyphal elongation to assist in macrophage killing and escape from the immune cells (Waldorf, 1989; Schöbel *et al.*, 2007). Therefore, it is possible that various carbon utilization pathways (e.g., methylcitrate cycle) could work together and compensate for the loss of a functional glyoxylate cycle (Ibrahim-Granet *et al.*, 2008; Dagenais and Keller, 2009). Removal of the glyoxylate cycle key enzyme genes also renders *C. neoformans* inability in utilization of certain carbon sources such as ethanol and acetate. Similar to *A. fumigatus*, deletion of *ICL1* and *MLS1* does not appear to affect the virulence of *C. neoformans* (Rude *et al.*, 2002; Idnurm *et al.*, 2007). The glyoxylate cycle is only indispensable for the virulence of *Candida* species, and this could be attributed to the long history of association and evolution of this fungal pathogen with the host. While both *Aspergillus* and *Cryptococcus* species can be found in the environment and within a host, *Candida* species lacks any apparent environmental reservoir and can only be found in the mammalian hosts (Kadosh and Lopez-Ribot, 2013), which may explain the different approaches employed by these fungal pathogens in alternative carbon utilization.

Gluconeogenesis

Gluconeogenesis is typically regarded as a reversal of glycolysis, albeit with multiple variations that distinguish the two pathways. Gluconeogenesis is a metabolic process responsible for the biosynthesis of glucose from non-carbohydrate precursors. These precursors include fatty acids, lactate, acetate, oxaloacetate, ethanol, glycerol, and glucogenic amino acids. Like the TCA and glyoxylate cycles, a large number of metabolic enzymes are identical to both glycolysis and gluconeogenesis (Turcotte *et al.*, 2010), while only two enzymes, phosphoenolpyruvate carboxykinase (EC 4.1.1.32) and fructose-1,6-bisphosphatase (EC 3.1.3.11) are exclusive to gluconeogenesis (Eschrich *et al.*, 2002). In fungi, both glycolytic and gluconeogenic pathways are regulated so that only one of the pathways is active at a time while the other remains relatively idle to prevent futile cycle, and these regulations are essentially controlled by the availability of glucose (activation of glycolysis) or non-fermentable alternative carbon sources (activation of gluconeogenesis) (Berg *et al.*, 2002). Following the flux through the glyoxylate cycle, oxaloacetate produced from alternative carbon utilization can be converted into phosphoenolpyruvate by the enzyme phosphoenolpyruvate carboxykinase (Lorenz *et al.*, 2004; Hynes *et al.*, 2007). Alternative carbon sources such as glycerol (in the form of GA3P), lactate (in the form of pyruvate), acetate, ethanol and fatty acids (in the form of oxaloacetate) all serve as potential precursors to fuel gluconeogenesis. Fructose-1,6-

bisphosphatase catalyzes the conversion of fructose-1,6-bisphosphate to fructose-6-phosphate at the final step in formation of hexose monophosphate (Lorenz *et al.*, 2004; Hynes *et al.*, 2007). In summary, the three interrelated metabolic networks (beta-oxidation, the glyoxylate cycle and gluconeogenesis) join forces to enable alternative carbon metabolism in medically-important fungi. This greatly enhances the survival of these fungi in many host niches in human body that have limited glucose supply.

Disruption of the gluconeogenic-specific enzyme gene, *PCK1* (phosphoenolpyruvate carboxykinase) attenuated the virulence of *C. albicans* in mice, while re-introduction of the wild-type *PCK1* restored the fungal virulence (Barelle *et al.*, 2006). On the other hand, Ramírez and Lorenz (2007) reported that disruption of *FBP1* (fructose-1,6-bisphosphatase) greatly affected the growth of *C. albicans* on glycerol, lactate, acetate, ethanol and oleic acid. Furthermore, loss of *FBP1* significantly reduced the virulence of *C. albicans* in vivo, as up to 30% of mice still survived after 20 days of infection, while all mice infected with the wild-type *C. albicans* succumbed to death after 10 days (Ramírez and Lorenz, 2007). Similar to *C. albicans*, deletion of *PCK1* in *H. capsulatum* impaired the ability of this fungi to grow within macrophages and in vivo virulence (Shen *et al.*, 2020). Being a nearly exclusive intracellular fungal pathogen, *H. capsulatum* required utilization of gluconeogenic intermediates via gluconeogenesis for survival and proliferation in the host (Deepe *et al.*, 2008; Shen *et al.*, 2020). Targeted knockout of *PCK1* also considerably reduced the virulence of *C. neoformans* mutant as compared to the wild-type strain in a mouse inhalation model of cryptococcosis, and complementation of wild-type *PCK1* restored its full virulence (Panepinto *et al.*, 2005). However, Price *et al.* (2011) reported that although *PCK1* is highly up-regulated in *Cryptococcus* infection, this gluconeogenic enzyme gene is not required for the persistence and viability of this fungal pathogen in rabbit cerebrospinal fluid model of cryptococcosis. As for *A. fumigatus*, phosphoenolpyruvate carboxykinase-encoding gene *acuF* has been reported to be up-regulated in response to stress conditions such as heat-shock and hypoxia (Do *et al.*, 2009; Barker *et al.*, 2012). However, the role of this gluconeogenic gene in the virulence of *A. fumigatus* still remains to be determined.

Glucose and Alternative Carbon Metabolism: A Prospective Therapeutic Target for Fungal Diseases

It is undeniable that carbon metabolism is integral to the pathogenicity of human fungal pathogen, as changes in the metabolic adaptation greatly impact the fungal pathogenicity at multiple levels (Brown *et al.*, 2014). Lately, research have been focusing on targeting these metabolic pathways in searching for potential antifungal targets (Chen *et al.*, 2020). Although the development of effective antifungals is often hindered by the eukaryotic biology these fungi share with human, there are still a number of fungal-exclusive metabolic pathways that can be targeted for drug development (Zhang *et al.*, 2012; Kaldorf *et al.*, 2016). One of the major pathways essential to fungal pathogens like *C. albicans* and *C. glabrata* that is not found in human is the glyoxylate cycle (Icl1 and Mls1) (Lorenz and Fink, 2001; Ramírez and Lorenz, 2007; Chew *et al.*, 2019b). Multiple studies have demonstrated that potential inhibitors such as cadiolides E and G-1, caffeic acid, apigenin, rosmarinic acid, mohangamides A and B, suvanine sesterterpenes and monoterpenoid perillyl alcohol (PA) are able to inhibit *C. albicans* isocitrate lyase activity (Ahn *et al.*, 2013; Cheah *et al.*, 2014; Lee *et al.*, 2014; Bae *et al.*, 2015; Ansari *et al.*, 2018). In addition, Ansari *et al.* (2018) showed that PA inhibited *C. albicans* malate synthase activity and mRNA expression. Furthermore, it has been reported that four β -carboline alkaloid compounds also inhibited malate synthase from *Paracoccidioides* (Costa *et al.*, 2015). Several synthetic isocitrate lyase inhibitors such as itaconate, 3-nitropropionate and 3-bromopyruvate have been previously described (McFadden and Purohit, 1977; Schloss and Cleland, 1982; Ko and McFadden, 1990). These inhibitors serve as structural analogs for intermediates of the glyoxylate cycle – succinate and glyoxylate. However, these potential inhibitors have not been introduced as antimicrobials for human use, mainly due to their toxicity and detrimental effects to other metabolic enzymes in vivo (Lee *et al.*, 2015).

Other carbon metabolic pathways required for glucose and alternative carbon metabolism also harbored many potential therapeutic targets for fungal diseases. Among the components that are involved in these pathways are glucose sensors and transporters (e.g., Snf3, Rgt2, Hgt4), glycolytic enzymes (e.g., pyruvate kinase, enolase, hexokinases), gluconeogenic enzymes (e.g., Fbp1 and Pck1), and enzymes for beta-oxidation of fatty acid (Eschrich *et al.*, 2002; Barelle *et al.*, 2006; Brown *et al.*, 2006; Piekarska *et al.*, 2006; Ramírez and Lorenz, 2007; Ko *et al.*, 2013; Ng *et al.*, 2015; Laurian *et al.*, 2019). The potential antifungal targets based on these metabolic pathways of human fungal pathogen (*C. albicans*) has been discussed and summarized previously (Chen *et al.*, 2020). Nevertheless, the suitability and feasibility of most of these potential targets or inhibitors to be developed into full-fledged antifungals still remain to be determined, as fungi are more closely-related to human which represent a key fundamental challenge in drug development (Roemer and Krysan, 2014). Many inhibitors that are toxic to fungi are most probably also toxic to human. Currently, fungal-specific structures are the prime target for most of the major classes of antifungals (polyenes, azoles and echinocandins) commonly used (Roemer and Krysan, 2014). After identification of a potential fungal-specific drug target, it is crucial that the strategies used for antifungal development should focus on maximizing the drug effectiveness and minimizing the drug toxicity and adverse effects to the host. Also, it is also important that the novel antifungal agents targeting carbon metabolism can overcome the issue of fungal resistance for a better management of patients affected by fungal diseases.

Conclusion and Future Prospects

The knowledge and understanding of glucose and alternative carbon sources metabolism in medically important fungi have increased and deepened over the years. Appreciating these physiological processes which confer metabolic fitness to these fungi have partially lent to opening up of finding novel approaches in tackling the impending slow discovery and development of new

antifungal drugs. Though much has been discovered about these metabolic processes, it is an ongoing task as we are experiencing increasing number of novel fungal species that cause infections among us with unique and distinct types of metabolism. Needless to mention, with the growing advancements in medical knowledge and technologies, i.e., cancer treatments, organ and tissue transplantation, and etc. which render human population to have a longer life span, the number of immunocompromised and immunosuppressed individuals will also increase in tandem with it. The recent three to four decades have seen such trend but unfortunately, the awareness and research funding on fungal infections especially on invasive types have not caught up with it. In addition, the urbanization and industrialization activities and opening up of forest areas for human habitation that affect climate change has accelerated human encounter with novel fungal species which are generally known to be highly resistant to existing antifungal drugs. In our race to acquire more information, mountainous tasks await us. One of the challenges that we need to overcome is to be able to speed up and translate all these information and data into impactful applications. Till to date, there has been little or no significant outcome from these investigations to reduce the burden of mortality and morbidity due to fungal infections. Looking from that perspectives, there are questions that need further deliberation. The utilization of glucose and other alternative carbon sources by fungal pathogens is “more than meets the eye”. It goes beyond meeting the energy demand of the pathogens. Most studies on carbon metabolism related genes are based on investigating their monogenic effects and a handful of them looked into two and more genes. As expounded in the earlier paragraphs, many metabolism-related genes have yet to be fully discovered and functionally characterized. There are also instances where gene homologs of various fungal pathogens perform different functions. On another note, there are more and more accumulating transcriptomics data that are made available in the primary and secondary bioinformatics databases. One strategy is to combine and perform deeper analysis of these data utilizing advanced software where the interconnectedness of the various carbon metabolic pathways can be better appreciated and manipulated. Last but not least, again on bioinformatics front in addition to wet lab experiments, *in silico* experimentation on testing various carbon sources (not just one at a time) with varying ratio that mimic host niches will definitely spur further understanding of glucose and alternative carbon metabolism in medically important fungal pathogens.

Ergosterol Synthesis

Somanon Bhattacharya, Stony Brook University, New York, United States

Introduction

Sterols are important components of eukaryotic cell and mitochondrial membranes maintaining membrane fluidity, structure, function, and permeability. According to their origin, sterols are broadly classified into three types. First, the animal sterols, most important of which is cholesterol. Cholesterol aids in synthesis of cell membranes, bile acids, vitamin D and steroid hormones. Second, phytosterols, which are plant sterols, most important of which are stigmasterol, sitosterol and campesterol (Jorda and Puig, 2020; Hu *et al.*, 2017). These phytosterols help in maintaining proper plant growth and development. Plants also contain cholesterol especially in seeds, roots, stems, and leaves. Third kind of sterol is fungisterol, which is present in fungi. Ergosterol is a unique fungisterol present in the cell membrane within microdomains called lipid rafts. These lipid rafts are synthesized by fusion of sphingolipids and sterols. Lipid rafts are enriched with many biologically important molecules that include ion pumps (sodium and potassium pumps), multi-drug resistance (MDR) pumps, and nutrient transporters (Bhattacharya *et al.*, 2018). These rafts are critical for proper functioning of the cells, and abnormal cellular ergosterol levels cause severe growth defects in response to different environmental stressors (Bhattacharya *et al.*, 2018). Recent studies demonstrated that ergosterol can induce host cell pyroptosis. Pyroptosis is a necrotic and inflammatory programmed cell death induced by inflammatory caspases (Jorda and Puig, 2020; Koselny *et al.*, 2018; Rodrigues, 2018). Besides cell and mitochondrial membrane, ergosterols are also present in vacuoles, peroxisomes, and endoplasmic reticulum (ER). The physiological functions of ergosterol are described below:

Physiological Function of Ergosterol

As mentioned above, ergosterol is unique to fungi and is an integral part of the fungal cell and the mitochondrial membranes. In the cell membrane, ergosterol stabilizes the membrane by interacting with sphingolipids and regulating membrane structure, fluidity, and permeability (Bhattacharya *et al.*, 2018). Ergosterol fuses with sphingolipids to produce lipid rafts, which host important metabolic enzymes and membrane transporters. These transporters are crucial for exporting xenobiotics, toxic compounds, ions and drugs from the cell thereby preventing cellular damage. Additionally, ergosterol can alter cell membrane mobility affecting phospholipase transport. Besides transport, ergosterol can disrupt nutrient absorption by regulating the activities of membrane bound ATPase (Hu *et al.*, 2017). Hence, maintenance of cellular ergosterol levels is crucial for proper cellular functions. Ergosterol levels are maintained by sterol pools, which are composed of lipid droplets that store ergosterol. Proper ergosterol levels are also important for stress response. For example, during ethanol treatment, baker's yeast, *Saccharomyces cerevisiae* elevates cellular ergosterol levels and protects its cell membrane from any damages. Conversely, when antifungal drugs inhibit ergosterol biosynthesis, the yeast cells become significantly more sensitive to osmotic and salt stresses (Hu *et al.*, 2017; Bhattacharya *et al.*, 2018). Addition of ergosterol in the growth media significantly increases yeast cells' tolerance to osmotic stress (Hu *et al.*, 2017). Further, cellular ergosterol levels are also critical for hypoxic and temperature stress response. For example, *S. cerevisiae* cells with disrupted ergosterol biosynthesis were temperature sensitive (Hu *et al.*, 2017). Additionally, cellular ergosterol levels can elevate in response to hypoxic conditions causing yeast cells to grow and proliferate properly (Hu *et al.*, 2017). A recent study has linked ergosterol with host macrophage pyroptosis. Pyroptosis is a proinflammatory form of programmed cell death triggered by inflammasome-mediated activation (Koselny *et al.*, 2018; Rodrigues, 2018). The study identified several genes in the ergosterol biosynthesis pathway that participate in the induction of pyroptosis-related macrophage lysis (Koselny *et al.*, 2018).

Ergosterol Biosynthesis

Ergosterol is biosynthesized in ER by a cascade of 25 biosynthesis enzymes (Bhattacharya *et al.*, 2018). The pathway is conserved in different pathogenic and non-pathogenic fungi. For simplicity, this chapter describes ergosterol biosynthesis in model organism *S. cerevisiae*. Ergosterol biosynthesis is extensively studied in *S. cerevisiae*. This biosynthesis pathway is broadly divided into two parts: (1) Mevalonate pathway (MVP) and (2) Late pathway (Fig. 1). The MVP uses acetyl CoA as a substrate to synthesize farnesyl pyrophosphate (FPP) (Bhattacharya *et al.*, 2018). The first step of the pathway involves condensation of two acetyl-CoA groups to form acetoacetyl-CoA (Fig. 1). This step is catalyzed by acetoacetyl-CoA thiolase, which is encoded by *ERG10* in baker's yeast *Saccharomyces cerevisiae* (Fig. 1). The enzyme is also present in various fungi including *Candida sp.*, *Aspergillus sp.*, *Cryptococcus sp.*, *Schizosaccharomyces sp.*, and several other pathogenic and non-pathogenic fungi. The next step in MVP involves the synthesis of 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA). This step involves condensation of another acetyl-CoA molecule with

Fig. 1 Ergosterol Biosynthesis Pathway: A cascade of 25 enzymes are responsible for synthesis of ergosterol. The pathway is divided into two parts; (a) Mevalonate Pathway (MVP) and (b) Late Pathway. MVP uses Acetyl-CoA as the substrate to synthesize FPP (yellow text). FPP is the precursor for many metabolic processes represented in the blue box. Late pathway uses FPP to synthesize ergosterol. The rate limiting steps in the ergosterol synthesis pathway is depicted with red shaded box. Yellow stars signify that these reactions require ATP. Different ergosterol inhibitors are listed with red texts. The enzyme complex is depicted by blue shaded box. The steps in the ergosterol synthesis affected by heme, oxygen and iron are also marked.

acetoacetyl-CoA in an enzymatic reaction catalyzed by HMG-CoA synthase. The enzyme is encoded by *ERG13* in *S. cerevisiae* (Fig. 1) and is present in different fungi.

The next step involves an important rate-limiting step in MVP (Veen *et al.*, 2003). In this step, HMG-CoA reductase uses 2 molecules of NADPH to reduce substrate HMG-CoA to mevalonate (Fig. 1). The reductase enzyme has two paralogs in *S. cerevisiae* namely Hmg1p and Hmg2p. These paralogs are synthetic lethal, which means that deletion of both of the genes encoding these paralogs result in cell death (Bhattacharya *et al.*, 2018). Besides *S. cerevisiae*, this enzyme is also present in other pathogenic and non-pathogenic fungi. The enzyme is an important target for sterol synthesis inhibitory drugs, the statins (Bhattacharya *et al.*, 2018). In the next steps, mevalonate is first converted to mevalonate 5-phosphate and then to mevalonate diphosphate by two phosphorylation reactions catalyzed by enzymes mevalonate kinase and phosphomevalonate kinase respectively. These enzymes are encoded by *ERG8* and *ERG12* genes in *S. cerevisiae* respectively (Fig. 1). Both the enzymatic reactions are ATP-dependent. Mevalonate diphosphate then undergoes dehydration-decarboxylation in an ATP-dependent enzymatic reaction catalyzed by mevalonate pyrophosphate decarboxylase. The resulting product is isopentenyl pyrophosphate (IPP). The carboxylase is encoded by *ERG19/MVD1* in *S. cerevisiae*.

Next, IPP-dimethylallyl diphosphate isomerase converts IPP to dimethylallyl diphosphate (DMAPP). The enzyme is encoded by *IDI1* in *S. cerevisiae* (Fig. 1). DMAPP serves as the precursor of geranyl diphosphate (GPP) with the help of GPP-synthase enzyme. In this reaction, coupling of IPP and DMAPP occurs to produce GPP. GPP is further elongated by FPP-synthase to produce FPP, the final product of the MVP. GPP-synthase and FPP-synthase are encoded by *ERG20* in *S. cerevisiae*.

FPP is an important metabolic intermediate that aids in biosynthesis of heme, ubiquinone, dolichol, sterols and prenylated proteins (Fig. 1). These products are used as intermediates for many metabolic processes. For example, ubiquinones play a central role in mitochondrial respiration, while dolichols are inserted in ER and serve as glycosyl carrier during protein glycosylation.

In *S. cerevisiae* and related yeasts, all the enzymes in the mevalonate pathway are essential for cell growth and development (Bhattacharya *et al.*, 2018). These enzymes are distributed in several cellular compartments that include cytoplasm, ER, mitochondria and glycosomes. Most of these enzymes require oxygen and hence fungi cannot survive anaerobically without ergosterol supplementation (Zavrel *et al.*, 2013).

After MVP, ergosterol biosynthesis enters the late pathway (LP, Fig. 1). This pathway commences with the conversion of FPP to squalene. This is an enzymatic reaction catalyzed by squalene synthase. The enzyme aids in coupling of two FPP moieties to synthesize squalene. Squalene synthase is encoded by *ERG9* gene in *S. cerevisiae* and is present in wide varieties of fungi. The gene is essential for fungal growth and fungi cannot survive in absence of *ERG9* unless supplemented with ergosterol. Next step in LP is an important rate-limiting step in the pathway during which squalene epoxide is synthesized (Veen *et al.*, 2003). The enzyme that catalyzes this reaction is squalene epoxidase, which is encoded by *ERG1* in *S. cerevisiae*. The enzyme causes epoxidation of squalene to 2–3 oxidosqualene and is a target of antifungals, allylamines (terbinafine) (Bhattacharya *et al.*, 2020b). *ERG1* is an essential gene and cells lacking *ERG1* cannot survive unless supplemented with ergosterol. Repression of this enzyme causes aberrant mitochondrial morphology but increased competitive fitness. The enzyme requires oxygen and is localized in ER and lipid particles (Leber *et al.*, 1998). Following epoxidation, lanosterol is synthesized with the help of lanosterol synthase enzyme. The enzyme is localized in lipid bodies and is encoded by *ERG7* in *S. cerevisiae* and catalyzes the cyclization of 2–3 oxidosqualene to produce lanosterol. *ERG7* is an essential gene and required for fungal growth.

Lanosterol is an important precursor in biosynthesis of ergosterol. Lanosterol is then converted to 4,4-dimethylcholesta 8,14,24 trienol in an important enzymatic reaction catalyzed by 14 α demethylase enzyme. The enzyme belongs to cytochrome p450 family and requires heme and oxygen for proper functioning. The enzyme catalyzes C14 demethylation of lanosterol to produce 4,4-dimethylcholesta 8,14,24 trienol. This step is another important rate-limiting step and the demethylase enzyme is the target for most common class of antifungals, the azoles (Bhattacharya *et al.*, 2018; Veen *et al.*, 2003; Bhattacharya *et al.*, 2020b). The demethylase enzyme is localized in ER and is encoded by *ERG11* in *S. cerevisiae*. The enzyme functions in association with another enzyme, NADP-cytochrome 450 reductase. The reductase is encoded by *NCP1* in *S. cerevisiae* and is regulated by the demethylase enzyme (Bhattacharya *et al.*, 2018).

In the next step, the trienol is reduced to 4,4-dimethyl zymosterol by C-14 sterol reductase enzyme. This enzyme is encoded by *ERG24* in *S. cerevisiae* and is a target for antifungals morpholines (Bhattacharya *et al.*, 2020b). The cells lacking this enzyme produces an abnormal sterol intermediate, ignosterol and cannot grow in nutrient rich media unless supplemented with calcium (Crowley *et al.*, 1996). Dimethyl zymosterol is then processed by a complex of 5 enzymes to produce zymosterol. These enzymes include C-4 methyl sterol oxidase, C-3 sterol dehydrogenase, 3 keto sterol reductase, and ergosterol biosynthesis protein 28. In *S. cerevisiae*, ergosterol biosynthetic protein 28 is encoded by *ERG28* and aid in protein-protein interactions between C-3 sterol dehydrogenase and 3 keto sterol reductase (Gachotte *et al.*, 2001). The dehydrogenase and reductase are encoded by *ERG26* and *ERG27* respectively and are localized in ER.

Zymosterol is then further processed to synthesize fecosterol. Delta(24)-sterol C methyltransferase enzyme catalyzes the production of fecosterol from zymosterol. The enzyme is encoded by *ERG6* in *S. cerevisiae*. The transferase enzyme is localized in several regions that include lipid particles, mitochondrial outer membrane, and plasma membrane associated ER (Parks *et al.*, 1995). Fungi can survive in absence of this enzyme but have severe growth defects in response to various environmental stressors (Bhattacharya *et al.*, 2018).

Fecosterol is then converted to episterol by C-8 sterol isomerase encoded by *ERG2* in *S. cerevisiae*. The enzyme catalyzes the isomerization of delta 8 double bond to delta 7 position to produce episterol. Fungal cells can survive in absence of this enzyme but accumulate aberrant sterol intermediates and show severe growth defects against different environmental stressors (Bhattacharya *et al.*, 2018). Episterol is then processed to produce ergosta 5,7,24(28) trienol in an enzymatic reaction catalyzed by C5-sterol desaturase. The enzyme is encoded by *ERG3* in *S. cerevisiae*. The desaturase is a glycoprotein that introduces C5(6) double bond in episterol. Fungal cells can survive in absence of this enzyme but show severe growth defects to different environmental stressors (Bhattacharya *et al.*, 2018).

Finally, the trienol is further processed by two enzymes, C-22 sterol desaturase and C24(28) sterol reductase to produce ergosterol. The two enzymes are encoded by *ERG5* and *ERG4* respectively in *S. cerevisiae*. The desaturase enzyme is a cytochrome p450 enzyme that catalyzes the formation of C22(23) double bond in the side chain during ergosterol biosynthesis. The reductase catalyzes the final step in the ergosterol biosynthesis. The fungal cells can survive in absence of these enzymes.

Subcellular Localization of Ergosterol Enzymes

Though ergosterol biosynthesis occurs in ER, the biosynthesis enzymes are localized in several cellular compartments that include ER, cytoplasm, glycosomes, lipid particles and mitochondria (Jorda and Puig, 2020). For example, ergosterol enzymes Erg1p, Erg7p, Erg27p and Erg6p are localized in both lipid particles and ER (Kristan and Rizner, 2012; Mullner *et al.*, 2004). The subcellular localization of the ergosterol enzymes determine their functions. For example, Erg1p is localized in both ER and lipid particles, however, the enzyme is only active when localized in ER (Leber *et al.*, 1998). When ergosterol levels are low due to iron

deficiency, Erg1p is exclusively localized in ER, where it is activated (Shakoury-Elizeh *et al.*, 2010). Erg7p and Erg27p are also located in two subcellular regions, ER and lipid particles. Erg27p binds with Erg7p in lipid particles and is rapidly migrated to ER when mitochondrial respiration is blocked (Cirigliano *et al.*, 2019). Erg11p and Erg24p are localized in ER. Erg28p tethers the C-4 demethylation enzyme complex of Erg25p-Erg26p-Erg27p to ER and also acts as a bridge to Erg6p enzyme for synthesis of ergosterol (Mo *et al.*, 2004). Erg6p is localized in both lipid particles, ER, cytoplasm and mitochondria. The ergosterol enzymes in the later part of the pathway, Erg2p, Erg3p, Erg4p and Erg5p are all localized in the ER (Jorda and Puig, 2020).

Regulation of Ergosterol Synthesis

Appropriate ergosterol content is required for the maintenance of lipid bi-layer and also for adequate environmental stress response (Jorda and Puig, 2020). Hence, ergosterol biosynthesis is tightly regulated. The different ways by which fungal cells regulate ergosterol synthesis are described below:

Post-Translational Feedback Regulation

As described above, the ergosterol biosynthesis pathway comprises of three rate-limiting steps. The first rate-limiting step is the reduction of HMG-CoA to mevalonate by HMG-CoA reductase enzymes, Hmg1p and Hmg2p. Regulation of this step is extremely important since this step is not only essential for the synthesis of ergosterol but also critical for mevalonate derived metabolites (Jorda and Puig, 2020; Bhattacharya *et al.*, 2018). In *S. cerevisiae*, increased oxysterol triggers degradation of Hmg2 enzyme through ubiquitination. The process is mediated by E3 ligase Hrd1p and E2 ubiquitin conjugating enzyme Ubc7p. Hmg2p is ER localized protein and upon initiation of ubiquitination, are released from ER to cytoplasm, where they are degraded by proteasomes (Hampton *et al.*, 1996; Hampton and Bhakta, 1997).

The second rate-limiting step in the pathway is the step producing lanosterol. The step is catalyzed by squalene epoxidase enzyme encoded by *ERG1* in *S. cerevisiae*. This enzyme is also degraded in presence of excess lanosterol via ubiquitin ligase Doa10p. Regulation of this step is crucial to prevent the accumulation of toxic sterol intermediates (Jorda and Puig, 2020; Bhattacharya *et al.*, 2018; Foresti *et al.*, 2013).

Transcriptional Regulation

- Regulation by sterols:** Sterol availability regulates the transcription of genes encoding the ergosterol biosynthesis enzymes. Majority of the enzymes in the pathway are controlled by transcription factors that bind to 7-base pair DNA motifs known as sterol regulatory element (SRE), located in the promoter regions of their respective genes. In mammals, these transcription factors are called sterol regulatory element binding proteins (SREBP). SREBP is cleaved in the ER by SREBP cleavage activating protein (SCAP), which is activated when sterol is depleted. Most fungi contain homologs for SREBP and SCAP except *Saccharomyces sp.*, and *Candida sp.* They instead have Zn₂-Cys₆ binuclear cluster family of transcription factor called Upc2p. Upc2p has a paralog Ecm22p that arose due to whole genome duplication in *S. cerevisiae* (Zavrel *et al.*, 2013; Bhattacharya *et al.*, 2020b; Hoot *et al.*, 2010). N- terminal domain of Upc2p is the DNA binding domain that binds to the SRE regions in the promoter regions of ergosterol biosynthesis genes (Fig. 2). The c-terminal end of Upc2p binds to ergosterol and acts as an ergosterol sensor. In presence of ergosterol the transcription factor is switched off and retained in the cytosol. During ergosterol depletion, Upc2p undergoes structural changes exposing its nuclear localization signal (NLS). This causes the transport of Upc2p into nucleus, where it binds to the SRE regions of the promoters of ergosterol synthesis genes, resulting in their transcriptional activation. The c-terminus of Upc2p also contains the activator domain. During ergosterol dissociation, Upc2p undergoes conformational changes to expose the activator domain that can recruit downstream transcriptional Upc2p co-activators. A previous study showed that SAGA co-activator complex is recruited to the promoter of ergosterol synthesis genes to cause transcriptional activation (Fig. 2) (Dewhurst-Maridor *et al.*, 2017). This complex may act as a co-activator that Upc2p recruits to enhance the expression of ergosterol biosynthesis genes during sterol depletion.
- Regulation by oxygen:** Ergosterol biosynthesis requires heme and oxygen as cofactors. Hap1p is a heme and oxygen sensing transcription factor that regulate several ergosterol biosynthesis genes in *S. cerevisiae*. Under normal aerobic conditions (normoxia), Upc2p transcription factor requires the action of heme- bound Hap1p for basal level production of ergosterol. Heme bound Hap1p not only activates ergosterol biosynthesis genes but also activates DNA binding protein Rox1p. Rox1p along with Mot3p transcription factor serve as repressors for hypoxic genes, which are genes activated under low oxygen levels. These hypoxia-regulated genes allow proper utilization of oxygen under limited oxygen levels. A drop in oxygen levels causes decrease in heme and ergosterol levels that triggers the signaling pathways to induce the expression of ergosterol biosynthesis genes. Upc2p and Ecm22p are activated under hypoxic conditions causing increased expression of the genes in the ergosterol synthesis pathways. Besides, Upc2p is also responsible for sterol transport. Under hypoxic condition, upregulation of Upc2p leads to upregulation of sterol transporters Aus1p and Pdr11p. This results in uptake of sterols from the environment. This is true in fungi *S. cerevisiae* and *C. glabrata*, however, in *C. albicans* no sterol uptake was observed under hypoxic conditions (Zavrel *et al.*, 2013).

Fig. 2 Regulation of Ergosterol Synthesis under sterol-limiting condition: Upc2p contains a DNA-binding domain (DBD) with a nuclear localization signal (NLS) at its N-terminus. The C-terminus region contains sterol binding domain (SBD) to which ergosterol (Erg) binds and an activation loop (AL). Under sterol limiting condition, ergosterol is released from SBD, and SAGA complex is activated that binds to Upc2p resulting in conformational changes in Upc2p exposing the DBD of Upc2p. This causes transcription of ergosterol biosynthesis genes (*ERG* genes). The image was drawn with the help of BiorRender.com.

- *Regulation by osmotic stress:* High osmolarity glycerol (HOG) pathway regulates hyperosmotic stress response in yeast (Jorda and Puig, 2020). Under osmotic stress such as in presence of high salt, Hog1p induces the transcription of Mot3p that negatively regulates ergosterol biosynthesis genes. This results in rapid decrease in cellular ergosterol levels in response to osmotic stress that is necessary for stress adaptation. In presence of extracellular ergosterol, the cells become highly sensitive to osmotic stress while on the other hand when drugs inhibit ergosterol biosynthesis, the cells become more tolerant to osmotic stress (Jorda and Puig, 2020).
- *Regulation by iron availability:* Four steps during the ergosterol biosynthesis requires the availability of iron. These include the steps catalyzed by Erg11p, Erg5p, Erg25p and Erg3p. Iron deficiency causes decrease in ergosterol and zymosterol levels resulting in accumulation of squalene and lanosterol (Shakoury-Elizeh *et al.*, 2010). Squalene and lanosterol are substrates of Erg1p and Erg11p respectively. Erg11p activity decreases in response to scarce iron due to decrease in heme levels resulting in accumulation of lanosterol. This inhibits the function of Erg1p causing accumulation of squalene (Shakoury-Elizeh *et al.*, 2010). Transcriptomics in iron deprived conditions showed altered expression of several ergosterol biosynthesis genes (Puig *et al.*, 2005).

Different factors that regulate ergosterol synthesis are summarized in Fig. 3.

Inhibitors of Ergosterol Synthesis and Ergosterol Target

Due to uniqueness of ergosterol in fungi, several enzymes in the biosynthesis pathway are targets of many antifungals. These antifungals inhibit ergosterol biosynthesis and can produce toxic sterol intermediates. Different inhibitors of ergosterol synthesis are described below:

- *Azoles:* Azoles are the most common antifungal class that inhibits 14 α demethylase enzyme (Erg11p) in the ergosterol biosynthesis pathway (Fig. 4). The enzyme is the third rate-limiting step in the ergosterol biosynthesis pathway that converts lanosterol to 4,4-dimethylcholesta 8,14,24 trienol. The azoles inhibit the Erg11p causing other ergosterol biosynthesis enzymes to process lanosterol. The enzyme Delta(24)-sterol C methyltransferase (Erg6p) converts lanosterol to sterol intermediate eburicol. Eburicol is then converted to 14 α methyl fecosterol with the help of enzyme complex encoded by genes *ERG25*, *ERG26*, and *ERG27*. Next, C5-sterol desaturase enzyme (Erg3p) converts 14 α methyl fecosterol to toxic sterol intermediate, 14 α methylergosta 8, 24(28) dienol. The accumulation of toxic intermediate causes inhibition of fungal growth (Fig. 4) (Bhattacharya *et al.*, 2018; Bhattacharya *et al.*, 2020b). Besides toxic sterol production, azoles lower the ergosterol content of the cell thereby preventing the proper functioning of the cell membrane. Azoles also cause elevated mitochondrial reactive oxygen species (mROS) that can damage mitochondria eventually leading to mitophagy or autophagy (Delattin *et al.*, 2014).

Fig. 3 Regulation of Ergosterol synthesis by different environmental factors. The image was drawn with the help of BioRender.com.

Fig. 4 Mode of Action of Azoles: Azoles inhibit Erg11p in the ergosterol biosynthesis pathway causing production of fungistatic toxic sterol. The image was drawn with BioRender.com.

Azoles are broadly classified into two subclasses: (1) triazoles and (2) imidazoles. Triazoles contain three nitrogen group and includes azoles such as fluconazole, itraconazole, voriconazole, isavuconazole, and posaconazole (Bhattacharya *et al.*, 2020b). Fluconazole is the most common antifungal used in treating fungal infections. Imidazoles are azole subclass that contain two nitrogen rings and include azoles such as ketoconazole, clotrimazole, and miconazole (Bhattacharya *et al.*, 2020b).

Azoles are fungistatic drugs i.e., they can only inhibit fungal growth without killing, causing fungal cells to evolve resistance. Over several decades, extensive studies in different pathogenic fungi have been done to identify the different molecular mechanisms behind azole resistance. Most common azole resistance mechanism observed in *Candida sp.*, *Aspergillus sp.*,

Cryptococcus sp., and *S. cerevisiae* is overexpression of genes encoding membrane transporters (Bhattacharya *et al.*, 2020b, 2019, 2016; Chang *et al.*, 2018; Esquivel *et al.*, 2020; Bhattacharya and Fries, 2018). These membrane transporters are either ATP-dependent (ABC-transporters) or proton gradient dependent (MFS-transporters). These transporters export azoles from the cells thereby preventing cellular damage. These increased expression of both classes of efflux pumps are attributed to gain of function (GOF) mutations in their respective transcription factors, Tac1p and Mrr1p in *Candida sp.* (Bhattacharya *et al.*, 2020b; Whaley *et al.*, 2016; Morschhauser *et al.*, 2007; Kalkandelen *et al.*, 2015). These are zinc cluster (Zn_2 -Cys₆) transcription factors in which several GOFs are associated with increased azole resistance. For example, GOF mutations in *C. albicans* TAC1 that include T225A, V736A, N972D, N977D, G980E, and G980W were observed in fluconazole resistant clinical isolates (Bhattacharya *et al.*, 2020b; Coste *et al.*, 2006). GOF mutations in *C. albicans* MRR1 that include P683S and P683H were also reported in fluconazole resistant clinical isolates (Bhattacharya *et al.*, 2020b; Kalkandelen *et al.*, 2015; Dunkel *et al.*, 2008). Additionally, chromosomal alterations are also associated with azole resistance. For example, chromosomal alterations due to segmental aneuploidy causing two copies of the left arm of chromosome 5 was observed in azole resistant *C. albicans* clinical isolates. The left arm of chromosome 5 contains azole drug target encoding gene *ERG11* and transcription factor encoding gene *TAC1* (Selmecki *et al.*, 2006). Chromosomal alterations were also observed in fluconazole resistant *C. neoformans* (Stone *et al.*, 2019). Besides, increased copy number of genes *CDR1* (encoding ABC-transporter Cdr1p) and *ERG11* were observed in azole resistant generationally aged old cells of *C. auris* (Bhattacharya *et al.*, 2019, 2020a).

Azole resistance is also associated with altered ergosterol biosynthesis. One of the important resistance mechanisms is the overexpression of drug target encoding gene *ERG11* (Bhattacharya *et al.*, 2020b, 2016). As described above, Erg11p catalyzes an important rate-limiting step in the ergosterol biosynthesis pathway. Besides overexpression, point mutations in *ERG11* were also reported in azole resistant clinical isolates of *Candida sp.* For example, *ERG11* point mutations that include A61V, A114S, Y132F, Y132H, K143Q, K143R, Y257H, S405F, G448E, F449S, G464S, R467K, and I471T were reported in azole resistant *C. albicans* clinical isolates (Xiang *et al.*, 2013). Besides *ERG11* point mutations, mutations in *ERG3* are also associated with azole resistance. *ERG3* encodes C5 sterol desaturase as described above during ergosterol biosynthesis. This enzyme is also responsible for producing toxic sterol intermediate in presence of azoles. Mutations causing disruption of Erg3p function in *C. albicans* and point mutation, Q139A in *C. glabrata* are associated with azole resistance (Bhattacharya *et al.*, 2020b; Sanglard *et al.*, 2003; Yoo *et al.*, 2010). Mutations in *ERG6* also contributes to azole resistance. *ERG6* encodes $\Delta 24$ sterol C-methyl transferase, which is responsible for producing toxic sterol intermediate in presence of azoles. Disruption of the transferase activity causes azole resistance, increased membrane permeability and inefficient efflux pump activities (Bhattacharya *et al.*, 2020b; Anderson *et al.*, 2003; Akins, 2005; Xu *et al.*, 2007; Kodedova and Sychrova, 2015).

The GOF mutations in Upc2p, the transcription factor regulating majority of the ergosterol biosynthesis genes are also associated with azole resistance. These mutations include G648D, G648S, A643T, A643V, Y642F, G304R, A646V, and W478C were reported in azole resistant *C. albicans* clinical isolates (Flowers *et al.*, 2012). Majority of these mutations trigger overexpression of *ERG11*.

- **Allylamines:** These are the class of antifungals that target squalene epoxidase (Erg1p) in the ergosterol biosynthesis pathway. Erg1p catalyzes a rate limiting of the synthesis pathway step as described above. The most common antifungals of this class are terbinafine, flunarizine and naftifine of which terbinafine is commonly used in treating dermatophyte infections (Sanglard *et al.*, 2009). Terbinafine resistance has also been observed in dermatophytes, which resulted from point mutations in the gene encoding the squalene epoxidase enzyme. For example, in clinical isolates of dermatophyte, *Trichophyton mentagrophytes*, point mutations leading to amino-acid substitutions at positions Leu³⁹³, Phe³⁹⁷, Phe⁴¹⁵, and His⁴⁴⁰ in squalene epoxidase enzyme showed increased terbinafine resistance (Yamada *et al.*, 2017).
- **Morpholines:** These are the class of drugs that inhibit the ergosterol biosynthesis enzymes C-14 sterol reductase (Erg24p) and C-8 sterol isomerase (Erg2p). Morpholines include fenpropimorph, tridemorph, and morpholine, and are commonly used in agriculture. They exhibit toxicity to humans and are used in treating nail dermatophyte infections (Bhattacharya *et al.*, 2020b; Sanglard *et al.*, 2009; Shirwaikar *et al.*, 2008).
- **Polyenes:** This class of drugs include amphotericin B and nystatin. They bind to ergosterol in the membrane and form pores through which monovalent ions leak causing cell death (Efimova *et al.*, 2014). Amphotericin B is commonly used antifungal to treat systemic infections. Amphotericin B has more affinity towards Ergosterol than cholesterol (Bhattacharya *et al.*, 2020b). However, the drug has toxic effects affecting kidney. Disruption of ergosterol synthesis are associated with polyene resistance in *Candida sp.* For example, disruption of *ERG3* and *ERG6* lowered ergosterol levels and increased amphotericin B resistance in *Candida sp.* (Vandeputte *et al.*, 2012).

Conclusion

Ergosterol is a sterol unique to fungi and is important for fungal growth, proliferation, stress adaptations, and cellular detoxification. Thus, studying ergosterol biosynthesis is of great importance to understand fungal biology. Additionally, ergosterol is used as precursor for synthesizing steroidal drugs (Hu *et al.*, 2017). Yeast fermentation is the main source for production of ergosterol. Many molecular biology-based strategies have been used to increase the yield of ergosterol. These strategies include optimization of fermentation conditions, genetic manipulation of the ergosterol biosynthesis pathway, and screening for mutants

that yield high levels of ergosterol (Nahlik *et al.*, 2017). Besides ergosterol, zymosterol and lanosterol, the two important intermediates of ergosterol biosynthesis are used as emulsifiers and precursors of cholesterol lowering substances (Wriessnegger and Pichler, 2013). Artificial production of zymosterol and lanosterol are also carried out using genetic manipulations (Paramasivan and Mutturi, 2017). Metabolic manipulations of ergosterol biosynthesis pathway also aided in synthesizing terpenoids and steroids. For example, site directed mutagenesis of Upc2p (G888A), Erg20p (K197G), and Hmg2p (K6R) are used to produce terpenes, mono-terpenes, and mono,di-sequesterpenes (Wriessnegger and Pichler, 2013). Additionally, since ergosterol is unique to fungi, the each enzymatic step in the pathway is potential target for novel drug designing (Rodrigues, 2018). Thus, studying fungal ergosterol biosynthesis is very important for better understanding fungal biology, designing novel drug targets, and generating economically important steroids and terpenoid molecules.

Fungal Volatile Organic Compounds

Andrea Martinez and Joan W Bennett, Rutgers, The State University of New Jersey, New Brunswick, NJ, United States

Introduction

The term *volatile organic compound* (VOCs) encompasses all carbon-based, low molecular weight compounds that easily enter the gaseous state due to their low boiling point and high vapor pressure. When found in liquid form, they have a propensity to evaporate easily at ambient temperatures and pressures. When found in a solid phase, they can sublime into the gas phase. Some of the best-known VOCs include synthetics that result from industrial processes such as gasoline combustion, laboratory solvents (e.g., chloroform, toluene), or compounds released from household products such as epoxies and paints. Examples of specific VOCs commonly found in modern buildings include benzene, ethylene glycol, formaldehyde, methylene chloride, tetrachloroethylene, and xylene. At elevated concentrations these synthetic VOCs are toxic.

VOCs in nature are found as mixtures of different compounds and are generated by all living things. The best-known biogenic VOCs are produced by plants and are often perceived by their distinctive odors. Well known plant VOCs include the isoprenoids limonene, pinene and menthol that smell, respectively, citrusy, resinous and minty. Most fungal VOCs also have characteristic odors, and people usually recognize the smell of yeast fermentations or moldy basements even if they know nothing about the organisms producing the odor or the fact that odors are caused by volatile molecules.

The compound term *fungal VOCs* describes a large group of the easily volatilized carbon compounds that have been associated with members of the fungal kingdom. In nature, fungal VOCs are found as heterogeneous blends composed of varying amounts and concentrations of alcohols, aldehydes, esters, ketones, modified amino acids, furans, terpenes, as well as sulfur compounds and their derivatives. The single most famous fungal VOC, ethanol, is produced by yeasts during alcoholic fermentation. The single most common volatile from filamentous fungi, 1-octen-3-ol, is produced by the breakdown of linoleic acid.

The fungal kingdom is distinguished by its distinctive osmotrophic form of nutrition whereby extracellular enzymes are secreted to the environment, followed by the absorption of the externally “digested” nutritional products. Fungi are absorptive heterotrophs, or put more simply, fungi have their stomachs on the outside. Consequently, many of the compounds detected from analyses of fungal VOC are breakdown products of the nutrient source on which the fungus is growing, made by the action of nonspecific extracellular fungal enzymes. This means that detection of a particular volatile compound in a profile sampled from the headspaces of a fungal source does not necessarily imply that the compound is endogenously produced within the fungus. Substrates are an extremely important determinant of the total volatile profile that is detected from a given species. Moreover, many endogenously produced fungal VOCs are by-products of primary metabolism generated during amino acid or fatty acid catabolism. For example, the respective transamination of valine, isoleucine, and leucine leads to the production of 2-methylpropanal, 2-methylbutanal, and 3-methylbutanal, all common members of fungal VOC profiles.

VOC profiles detected from fungi are extremely variable, changing not only with species, but with growth parameters, age of the fungal colony, and the method used for analysis and identification. The enormous difference associated with these variables makes it difficult to compare published research studies. Another important caveat about fungal VOCs is that most of these low molecular weight compounds are not unique to fungi but also are produced by different life forms. An online searchable database that encompasses microbial VOCs, including those from fungi is available from Lemfack and colleagues (see “Relevant Website section”).

Volatilome and Volatome

Recently, the jargon words *volatilome* or *volatome* have entered the scientific literature to describe the entire spectrum of volatiles detected during a given analysis from a particular source, as in “fungal volatilome” or “fungal volatome”. These synonymous terms usually are used without an accompanying stipulated definition.

What do these terms mean? Are authors correct in thinking that everyone understands their meaning in the same way?

Some biological etymology is pertinent here. The suffix “-ome” is used in two different but overlapping ways by different communities of biologists. Parsing these different usages reveals something of the complexity of studying volatile profiles. Since early in the 20th century, the word *biome* has been used by ecologists to encompass an entire complex community characterized by distinctive animal, microbial and plant species that are maintained under the climatic conditions of a given region and specific climate (e.g., aquatic, forest, grassland, desert, tundra, etc.). The second use of “-ome” finds its roots in genetics. In the early twentieth century, genomes were defined as the complete set of genetic information in an organism. In the late 20th century, the explosion of nucleic acid sequencing methods and other analytical techniques led to a proliferation of “-omics” word such as genomics, transcriptomics, and so on. Many readers, especially molecular biologists, assume that all jargon words containing the suffix “-ome” are an extension of the “-omes” used in molecular geneticists, i.e., *genome* (the entire set of DNA in an organism), *transcriptome* (usually used to refer to the RNA molecules expressed at a certain time under certain environmental conditions); the *metabolome* (the products of a biological reaction, including intermediates), and *exometabolome* (the extracellular metabolites).

However, while the *volatilome/volatome* is the complete collection of volatile metabolites, it is not necessarily the same thing as an *exometabolome*. The total sum of the volatiles from a fungal sample may include the products of a resident fungal microbiome, incidental degradation products of the substrate, artefacts of the assay process, and other small molecules that are not directly associated with the genome of the producing fungus. Therefore, we suggest that it is best to take a “big umbrella” approach to generating a stipulated definition of “*volatome /volatilome*”. Our stipulated definition encompasses the entire sample of volatile obtained from extracting a fungal source. This definitional frame encapsulates the endogenous products of the fungal metabolome (the “-ome” of genomics), the products of the resident bacterial and yeast microbiomes (the microbiome of ecologists), as well as the substrate degradation products released by fungal exogenous enzymes (the nonspecific products of fungal exoenzymes). Additionally, it can include the unrecognized artefacts of extraction and analytical techniques that may be present. Put simply, a fungal *volatome/volatilome* is all the VOCs in a particular sample of fungal origin, not just those encoded in some way by the fungal genome.

The word *microbiome* reflects a similar fusion of the two “-ome” meanings. Microbiome research is conducted by isolating nucleic acids from a sample, not by isolating the organisms. Nevertheless, as used in the scientific literature, *microbiome* simultaneously refers to all the microorganisms from a certain environment such as a soil sample or a part of the human body, as well as the combined genetic material of the microorganisms in a particular environment.

Some common VOCs such as 1-octen-3-ol, 3-octanone, and 2-pentylfuran are primarily synthesized by fungal genera. Other compounds such as dimethyl disulfide, acetic acid, 2-nonanone, dimethyl trisulfide, 2-undecanone, isovaleric acid, 2-tridecanone, propanoic acid, tend to be produced by bacteria and when detected in a fungal *volatome* are likely due to the presence of a resident bacterial microbiome growing on or in the fungus.

Finally, it is important to remember that all published data on fungal *volatilomes* are “snapshots.” They do not capture the dynamic nature of volatile emissions nor do they tell us much about changing populations in communities. Moreover, such *volatilomes* do not differentiate between the volatiles that may have little or nothing to do with the fungal *metabolome*, those produced by resident complex bacterial microbiomes and those that are not directly related to the genomes of either the bacteria or the fungi. The sections below highlight some important findings related to fungal *volatomes/volatilome* – broadly defined – and some individual fungal volatiles.

Chemical Analysis

VOCs are difficult to study. By definition, these small molecules easily enter the gas phase where they rapidly dissipate. As they disperse, they become less concentrated. The dilution effect increases with distance, and other factors associated with the experimental or natural environment. Not only are most VOCs present in only low concentrations, they are found as components of complex mixtures which necessitates separation, and further complicates their identification.

Early research on fungal VOCs depended on steam distillation coupled with liquid-liquid extraction, followed by concentration of individual compounds and chemical identification of the isolated compounds. Technical developments in gas chromatography and mass spectroscopy (GC-MS) have greatly expanded our knowledge of volatile chemistry and most VOCs are now studied by headspace analysis. Because GC-MS links the separation, identification and quantification steps, individual VOCs in complex mixtures can be identified more rapidly. Individual volatiles are identified by comparisons of mass spectra with authentic standards, chemical library spectra, and/or chromatographic retention indices. Examples of specialized versions of this general approach include proton-transfer-reaction mass spectrometry (PTR-MS); selected-ion flow-tube mass spectrometry (SIFT-MS); and time of flight mass spectrometry (GC-TOFMS). Perhaps the most broadly used method is solid phase microextraction (SPME) in which VOCs are concentrated on a portable fiber and later delivered to the input of a detector. Desorption occurs in the GC injector itself. SPME is convenient and combines extraction, concentration, and introduction.

The experimental objectives of the research in question often determine the methods used. The initial step for gas chromatographic analysis is the purging and trapping of the compounds in the volatile headspace. For isolation of individual compounds, absorbance materials with the desired binding qualities are used. The choice of solvent is another important aspect of volatile analysis because the solvent itself can influence the VOC profile. It is important to remember that the method used to analyze VOC profiles can alter the outcomes. Classical studies using exhaustive solvent extraction procedures and heat often yielded VOCs that are solvent degradation products produced during the extraction steps. With more contemporary methods, fewer artifacts are found but nevertheless they still can be introduced by solid sorbents used during headspace analysis and other steps of the analytical process.

In summary, the methods used for isolation and identification affect the results found. Sample preparation and methods used for separating, identifying and quantifying the VOCs have an impact on the kinds and amounts of VOCs detected.

Fungal VOCs as Odorants

In order for an odorant to be detected by the human olfactory system, the compound must be volatile. Macrofungi often emit distinctive odors and many guides for mushroom hunting mention characteristic odors. In particular, stinkhorns are infamous not only for their notable penile shape but also for their foul-smelling, fly-attracting fruiting bodies. Stinkhorns are said to smell like a

powerful combination of decaying meat and dog feces. Dominant VOCs include dimethyl sulfide and trimethyl sulfide, phenol, p-cresol and indole and skatole. Other mushrooms with unpleasant odors include *Gymnopus perforans*, which smells like rotten cabbage and *Cortinarius camphoratus*, which smells like rotten potatoes.

On the other hand, numerous macrofungi are known for their pleasant odors. *Agaricus subrufescens*, also called the royal sun *Agaricus*, has the fragrance of almonds; *Russula laurocerasi* smells like slightly “off” maraschino cherries; *Clitocybe odora* has an anise-like aroma; *Lactarius hibbardae* emits a distinct coconut smell; and the chanterelle *Cantharellus cibarius* smells like apricots. *Lactarius camphoratus* resembles fenugreek, which is a key ingredient in curries; *Inocybe lacera* is said to resemble the odor of human semen. *Cortinarius traganus* has a distinct odor resembling dried apples or pears and *Cortinarius violaceus* smells like cedar wood.

There are often significant differences in the type and concentration of VOCs detected from the same species. For fungi isolated from the natural world, the main variances detected by different studies are due to nutritional, regional and environmental differences in the place the fungi grew, as well as the freshness of the samples. The age of the sample and the way in which samples were stored also can have a big impact on VOCs detected.

Foods and Flavors

Volatile organic compounds play a large role in gastronomy. For example, sulfur-containing volatiles emitted by plants such as onions and garlic in the plant genus *Allium* are important for their aromatic and flavor profiles. These thiols are also utilized in many traditional medicines. Similar organosulfur compounds provide the source of aromas associated with popular edible fungi such as shiitake mushrooms and truffles.

The reputation of truffles as gourmet foods rests upon their singular aroma profiles. The distinctive odors are caused by a blend of volatile molecules, of which the most distinctive contain sulfur atoms. VOCs identified from different truffle species include 3-methyl-4,5-dihydrothiophene; bis(methylthio) methane; dimethyl disulfide and dimethyl sulfide. In addition, the aldehyde 2-octenal, and the alcohol 1-octen-3-ol have been found in both white and black truffles. Additional aromatic compounds from truffles include 2,3-butanedione, ethyl butyrate, 3-methyl-1-butanol and 3-ethyl-5-methylphenol. Some of the words that have been used to describe truffle volatiles compare their odor to a mixture of garlic, horseradish, and cabbage. Others descriptive terms include meaty, fruity, green apple, anise, rose, buttery, cotton candy, malty, wet forest, and cooked potatoes. The aroma also is said to have a slight taste of radish and a hint of hazelnut. The odors can range from mild to intense, and can vary from cheese-like, earthy, garlicky, pungent, to vanilla-like, creamy, and leathery.

Recent findings have shown that it is likely that the sulfur-containing volatiles of the truffle fruit body are made by the biotransformation of non-volatile precursors by the members of the truffle microbiome, i.e., the thiophene volatiles that give truffles their distinctive aroma are biosynthesized by microbiome bacteria that live in and on the truffle, but are not metabolic products of the truffle genome.

Many Asian food fermentations get their distinctive flavors and aromas from fungi. For example, tempeh, a popular vegan dish, is a sliceable loaf of soybeans or grain fermented with *Rhizopus oligospora*. The aroma of tempeh is described as nutty, mushroom-like and earthy. Dominant VOCs emitted by tempeh are ethanol, acetone, ethyl acetate, 2-butanone, 2-methyl-1-propanol, 3-methyl-1-butanol and 2-methyl-1-butanol. When barley is the substrate, acetaldehyde and 2-methyl-propanal are also produced; when soybeans were the substrate, 2-pentanone, methyl acetate, 2-butanol and 3-methyl-3-buten-1-ol were detected. Dominant VOCs from fermented fish miso include 2-methylbutanal, 3-methylbutanal, methional, isoamyl acetate, dimethyl disulfide, dimethyl trisulfide, 2,3-butanedione, 3-methylethyl butanoate, 3-methyl-1-butanol, ethyl hexanoate, 1-octen-3-ol, heptanol, heptanal and 2-undecanone. There is a growing realization that many fermented foods in which a filamentous fungus like *Rhizopus* or *Aspergillus* is a dominant organism are actually complex fermentations involving many species of yeasts and bacteria. The individual species participating in the microbial communities shifts with time, nutrient source, salt concentration and the like. The volatilome detected in the fermentation head space consequently will vary as these parameters change.

Biotechnology

Synthesized liquid versions of natural volatiles are used in the food industry for flavor enhancement as well as for components in cosmetic and pharmaceutical products. The US Food and Drug Administration defines *natural flavors* as flavor compounds extracted from live cells. In many cases volatile compounds are derived using yeasts or filamentous fungi to produce increased quantities of compounds that are produced less abundantly in plants. Such compounds can be utilized in foods and fragrances to duplicate natural plant-derived metabolites. Many fungal VOCs are “bioidentical” to flavors derived from plants. For example, the coconut odor volatile 6-pentyl- α -pyrone, produced by some *Trichoderma* species can be used to substitute for the same compound isolated from coconuts. Utilization of yeast in fermentation aroma cultivation is yet another commonplace example of the importance of VOCs in the food and beverage industry.

Fungal VOCs also show promise as components of bio-renewable fuel (“mycodiesel”). Various compounds made by fungi include the monoterpene 1,8-cineole, an octane derivative that has potential use as a fuel additive. In addition to alkanes and certain long-chain hydrocarbons, many fungal species produce ethylene, ethane, propane and propylene as well as terpenes and

isoprenoids. It is believed that fungi are an excellent platform for exploiting biosynthetic routes to hydrocarbon biofuels and biofuel precursors.

VOCs for Indirect Detection of Fungal Growth

People often become aware of the presence of fungi by their odors, even when they are not visible. The human olfactory system is a sensitive finding system for fungi. Without any specialized equipment, fungal odors frequently can be detected before visible fungal growth. People recognize that food has spoiled because of “off” odors. Water damaged buildings also have distinctive musty odors. In agriculture, sampling of VOCs in storage bins and silos can detect the presence of mycotoxigenic fungi. Modern technologies have been developed as indirect bioassays to detect the presence of “hidden” fungal growth. Thus, VOCs can be used to uncover fungal colonization by potentially harmful species in a variety of different environments. Because VOC detection is noninvasive, it is useful in many different contexts that range from the pharmaceutical and cosmetics industries to military installations. For example, scientists have taken advantage of this capability and use it as a way to detect food spoilage in commercial facilities and various kinds of factories. Potentially harmful fungi are detected by the presence of VOCs produced by the microbes and their interaction with the food source. Such “off” odors in foodstuffs have been used to identify spoilage in bakery products, jam factories, and silos of stored grains. Compounds such as 3-octanone, 1-octanol, and *e*-methyl-1-butanol have been associated with *Aspergillus* contamination of stored grains. Inside water damaged buildings, VOC detection provides a nondestructive way to find hidden mold growth behind walls and paneling, underneath carpeting, in air conditioning ducts, under wall paper and so forth. VOCs regularly identified from molds growing on building materials include 3-octanone, 1-octen-3-ol, 3-methyl-1-butanol, and 3-methyl furan.

Some plant diseases can also be identified by means of volatile detection such as the powdery mildew fungus *Uncinula necator* and the common bunt pathogen, *Tilletia caries*, the latter of which produces a characteristic fishy odor associated with trimethylamine.

Aside from being indicators of food spoilage, mycotoxin contamination, and indoor fungal growth, another use for VOCs is to identify human diseases. In classical times, physicians used their sense of smell to diagnose certain illnesses. Medical research has shown that exhaled breath or other VOC samples can be utilized to diagnose a variety of human illnesses. For example, some human cancers can be diagnosed by means of identifying VOC profiles unique to tumor cells and breath tests are accepted clinical tools in the diagnosis of certain gastroenterological diseases. Fungi that live on and within humans also emit volatile compounds that can be indicators of disease, and a promising use for VOC detection is in medical mycology. For example, 2-pentylfuran has been found in the breath of patients at early stages of *Aspergillus fumigatus* infection. *A. fumigatus* is the causative agent of invasive aspergillosis; unfortunately, this compound is also present in some foods such as soy milk and peanuts, which may lead to false positives by this detection mechanism. The sesquiterpene farnesene also has been suggested as a biomarker for *Aspergillus fumigatus* infection. It is posited that detection of species-specific volatile sesquiterpene metabolites of fungal origin can be found in the breath of patients with invasive aspergillosis. The challenge will be to identify stable and unique VOC profiles that reflect disease states. Studies have shown that the profile of volatile production depends on the nutritional environment. *A. fumigatus* produces a multiplicity of different VOCs. To date, scientists have been unable to identify key diagnostic VOCs by breath analysis but it remains a very promising area of research (Li *et al.*, 2016).

Artificial olfaction sensory technology is a method of VOC detection in which artificial or electronic noses (“e-noses”) are used in agricultural science, building science, and biomedical healthcare settings for this type of diagnostic approach. An electronic nose system typically contains a multisensor array with an information-processing unit, software with pattern-recognition algorithms, and reference-library databases. The sensor array is designed to respond to a wide assortment of chemical classes and to discriminate diverse mixtures of possible analytes. Identification and classification of individual mixtures of compounds is accomplished through recognition of the resultant unique aroma signature or “electronic fingerprint”. Future research is expected to make VOC sensing a more common approach to VOC testing.

Chemical Ecology

Many fungal VOCs mediate interspecific biotic interactions. Such bioactive VOCs have been called “infochemicals”. They influence growth, morphology, and population dynamics. Some serve specific ecological functions that include growth stimulation, or antibiosis, or as communication molecules for insects and other arthropods. Many fungal VOCs serve as signaling molecules for insects. They attract or repel arthropods, serve as aggregation agents, and/or are important in host location and attraction to food resources. Volatile compounds released from beneficial microbes present in the rhizosphere communicate with plants present in the ecosystem by increasing plant growth, influencing root morphology, inhibiting seed germination, and inducing systemic pathogen resistance. In addition to interacting with plants and arthropods, fungal VOCs also mediate interactions between various microbial populations (Hung *et al.*, 2015).

Plant VOCs are known to function to protect against herbivores, pathogens and competitors. They also are used to attract pollinators, disperse seeds, and attract mutualistic microbes. Fungal VOCs have not been the subject of as much research as plant VOCs, however, it is hypothesized that they play cognate roles in fungal life cycles. Like plants, fungi are not mobile. Therefore, it is theorized that members of both the plant and fungal kingdoms use volatiles to solve some of the ecological challenges that result from their immobility. These challenges include reproduction, dispersal, cooperation from mutualists, and protection from

competitors. Volatiles are useful in below-ground and above-ground signaling. In ecosystems containing a variety of microbes, the VOC profile is influenced by the various constituent members of the ecological community. Thus, the volatiles that arise during microbial growth influence the establishment and allocation of organisms within the ecological system. This arrangement of organisms is important in environments such as soil ecosystems where they play a role in competition, defense and recognition signaling. Volatile signaling takes place within an organism, between organisms, and across species of different kingdoms over narrow and wide ranges of communication.

Animals can detect a wide variety of volatile organic compounds. In particular, entomologists were among the first scientists to appreciate the power of volatile compound signaling and have developed a specialized vocabulary to describe molecules used in signaling. *Semiochemical* is the general term for signaling molecules. More specifically, *pheromones* are defined as volatiles involved in mediating interactions between the same species while *allelochemicals* mediate interactions between different species. Depending on concentrations, some fungal VOCs act as semiochemicals that mediate antagonistic and beneficial interactions between fungi and other life forms. Examples of volatiles known to function as semiochemicals include hexanal, (E)-2-hexenal, hexanoic acid, β -pinene, limonene, and 2-butyl-2-octenal which function as arthropod pheromones for uses such as signaling alarm and trail marking. Often the role of a volatile as a signaling molecule is context dependent. For example, mushroom alcohol (1-octen-3-ol) has been characterized as a semiochemical, a pheromone, a hormone and/or an allelochemical due to its varied roles in diverse interactions.

Blood-feeding insects have olfactory receptors present that serve as an integral part of the olfactory nervous system. These receptors bind to volatile compounds following their entry through the antennae. Many of the compounds that function as attractant and repellent semiochemicals are eight-carbon alcohol and ketone fungal volatiles. The same volatile compound can have diverse effects on different species. For example, VOCs released by decay fungi simultaneously attract bark beetles and are anti-attractant or “bypass” trophic signals for bark beetle predators. Interactions between insects and fungi include odor-mediated attraction and repulsion of insects to fungi and fungal substrates. Insect oviposition is also influenced by volatile compounds such as phenylacetaldehyde, 2-phenylethanol, dimethyl disulfide, citronellal, and norphytone. VOCs produced by fungi on pine weevil frass protect the insect’s eggs and influence odor-based detection of the host. Specifically, *Debaryomyces hansenii* produced methyl salicylate as a major compound which strongly reduced pine weevil’s attraction to the *Pinus sylvestris*. Artificial pheromones can be synthesized from known natural compounds and utilized in insect traps and potentially in the attraction of beneficial insects.

In nature, VOCs are found as composites containing multiple compounds at once, rather than a single, isolated volatile compound. For this reason, it is challenging to study the nature of volatile interactions because numerous variables within the experimental design may be difficult to control or compare.

VOCs as Antimicrobial Agents

Numerous fungal VOCs have antibacterial, antifungal, biostatic and/or fungistatic properties. *Mycofumigation* is the use of fungal VOCs to eradicate or inhibit other microbes, especially pathogenic species. The volatiles released by the cinnamon tree endophyte *Muscador albus* can kill several different pathogens. Similarly, the VOCs emitted by different *Trichoderma* species emit volatiles that inhibit growth of a variety of plant pathogens including *Alternaria brassicicola*, *Fusarium oxysporum*, *Phytophthora* spp., *Rhizoctonia solani*, *Sclerotinia sclerotiorum* and others.

In some instances, gas-phase molecules are involved in microbial quorum sensing. Quorum sensing is a type of cellular communication that bacteria use to modulate population responses to cell density. The volatile compound 3-hydroxyl palmitic acid methyl ester has been observed to function as a regulator of infection and virulence for the pathogenic bacteria *Ralstonia (Pseudomonas) solanacearum*, the causal agent of bacterial wilt in a variety of crops. Due to the limited opportunities of aqueous phase signaling on plant tissue surfaces and in soil environments, it is likely that additional examples of microbial volatile signaling are yet to be discovered.

Eight Carbon VOCs

Eight carbon VOCs are particularly characteristic of fungi (Combey et al., 2006). Mushroom alcohol, also known as matsutake alcohol, is the eight carbon alcohol 1-octen-3-ol, first identified many decades ago from *Tricholoma matsutake*. It is the single most frequently reported fungal volatile compound from filamentous species and is produced by the enzymatic oxidation and cleavage of linoleic acid. Other related fatty acid degradation products include 3-octanone, 3-octanol, octanol, and 1-octen-3-one, which are responsible for generating a typical mushroom smell. The human olfactory system can detect 1-octen-3-ol at concentrations as low as 10 $\mu\text{g}/\text{m}^3$. The chirality of 1-octen-3-ol can influence its odor, as is also true with other VOCs. Its S configuration has grassier and moldier characteristics than the R form. The R enantiomer, sometimes called “Roctenol” is the most common form of the compound in nature and is used commercially as an insect attractant.

Mushroom alcohol has a myriad of physiological properties and a wide range of effects and interactions in various systems. It has been shown to participate in fungal spore induction, production, and inhibition; plant development regulation; plant defense gene induction, and reactive oxygen species production. It is a self-inhibitor of spore germination in *Lecanicillium fungicola*, *Aspergillus nidulans* and *Penicillium paneum* and can be used as a treatment for “dry bubble disease” caused by the mycoparasite *Lecanicillium fungicola* which is widespread on cultivated button mushrooms.

When plants are treated with 1-octen-3-ol they show heightened expression of defense genes and changes in ethylene and jasmonic acid signaling and enhanced resistance to the plant pathogen, *Botrytis*. In addition, volatile phase 1-octen-3-ol is effective in reducing the growth of *Pseudogymnoascus destructans*, the causative agent of white nose syndrome in bats.

When found in human sweat, where it is likely a product of the human skin mycobiome, 1-octen-3-ol serves as a mosquito attractant. In addition to attracting insects, 1-octen-3-ol has also been observed to repel insects or act in mediating other entomological behaviors. For example, 1-octen-3-ol disrupts aggregation hormone responses in beetles. In combination with geosmin, 1-octen-3-ol functions as a millipede allomone used in defense signaling. In addition to its signaling properties, at higher concentrations 1-octen-3-ol functions as a toxin and has potentially harmful health effects. This has been demonstrated as respiratory rate depression in rats and toxicity to human embryonic cells in vitro. Furthermore, 1-octen-3-ol is among the compounds that may contribute what is known as “sick building syndrome” a phenomenon where symptoms such as fatigue, eye and skin irritation and respiratory issues arise from spending time indoors, specifically in mold contaminated buildings. Both mycotoxins and fungal VOCs are hypothesized to be among the causative agents of sick building syndrome. This syndrome is hypothesized to be a consequence of chronic exposure to the molds, mildews and other microbes inhabiting aging and damp buildings. Furthermore, exposure of *Drosophila melanogaster* to 1-octen-3-ol caused Parkinson-like symptoms including loss of dopamine neurons and disruption of vesicular monoamine transporter (VMAT) dopamine uptake in a fly model system.

Summary

Fungal volatile organic compounds (VOCs) are fungal associated, carbon-based, low molecular weight compounds that easily enter the gaseous state due to their low boiling point and high vapor pressure. In particular, 1-octen-3-ol, also known as mushroom alcohol or matsutake alcohol, is the single most common VOC isolated from filamentous fungi. Fungal volatiles from nature are isolated as mixtures of different compounds that change dynamically and vary with substrate, temperature, and other parameters of growth. The terms volatome and volatilome are used to describe all the VOCs found in a given chemical analysis of fungal VOCs, and encompass the reality that macrofungi and microfungi possess their own characteristic microbiomes of yeasts and bacteria.

Fungi often are detected by their smell because most of their VOCs are detected by the human olfactory system. When direct sampling techniques are not available, odors can identify the presence of mold contaminated foods and feeds, as well as buildings with hidden mold growth. Testing for volatile biomarkers in clinical samples promises a rapid, inexpensive and non-invasive disease screening tool in medical mycology.

Many macrofungi such as truffles produce blends of VOCs that are considered desirable in epicurean cuisine. Microscopic fungi including molds and yeasts also have distinctive odors profiles and some species have been cultivated and valued for the aromas they contribute to fermented food products such as mold ripened cheese, miso, soy sauce, and so forth. Certain fungal VOCs are used to imitate natural plant-derived scents. Others are used as indirect monitors to detect the presence of hidden fungal growth. Human breath analysis of key volatiles may provide a noninvasive early diagnostic test for invasive aspergillosis and other lung disease caused by fungi. Many fungal VOCs play important ecological roles in communication where they are an integral part of interspecies symbiotic interactions. Much is still to be discovered about the physiological function of VOCs and their involvement in intracellular and intercellular signaling. Moreover, many fungal VOCs remain uncharacterized, so there is considerable potential for new discoveries. From reproduction and defense within microbial communities – to disease detection, flavor enhancement and perhaps aromatherapy for humans – fungal VOCs are a near ubiquitous aspect of life with a wide array of possible future biotechnological functions.

Acknowledgments

We thank Hadeel Almaliki, Arati Inamdar, Shannon Morath, Sally Padhi, Kayla Pennerman and Karin Yin for informative discussions on fungal volatile organic compounds. We also acknowledge Isabelle Souza for help with manuscript preparation. Funding in the Bennett laboratory has been supported by the U. S. Department of Agriculture; the Fish and Wildlife Association; and the Sloan Foundation.

Introduction

Fungi are one of the most diverse and ubiquitous living groups, thus, its diversity, taxonomy, classification and applications are popular topics among interested groups. Nevertheless, ‘what are the real fungi’ is one of the debatable questions among mycological community. Currently, [Tedesoo et al. \(2018\)](#) and [Wijayawardene et al. \(2020a\)](#) accepted 19 phyla viz., *Aphelidiomycota*, *Ascomycota*, *Basidiobolomycota*, *Basidiomycota*, *Blastocladiomycota*, *Calcarisporiellomycota*, *Caulochytriomycota*, *Chytridiomycota*, *Entomophthoromycota*, *Entorrhizomycota*, *Glomeromycota*, *Kickxellomycota*, *Monoblepharomycota*, *Mortierellomycota*, *Mucoromycota*, *Neocallimastigomycota*, *Olpidiomycota*, *Rozellomycota* and *Zoopagomycota* in kingdom *Fungi* while excluding *Oomycota*, *Dictyosteliomycetes* and *Myxomycetes*.

In this chapter, we discuss the development of classification of Phylum *Ascomycota*, its current status and future perspectives.

Introduction to Ascomycota

Phylum *Ascomycota* is one of the largest phyla in Kingdom *Fungi*, which comprises ca. 9000 genera ([Wijayawardene et al., 2020a,b](#)). Phylum *Ascomycota* has been grouped in Sub Kingdom *Dikarya* with Phylum *Basidiomycota* ([Hibbett et al. 2007](#); [Tedesoo et al., 2018](#)). [Kendrick \(2000\)](#) listed four main characteristics of dikaryomycotan fungi; 1. The cell wall which comprises chitin; 2. Cell wall with cross walls, i.e., septa, except in yeasts; 3. Assimilative hyphae to fuse with one another (i.e., anastomosis) to exchange nuclei; and 4. Show unique nuclear phenomenon called dikaryon. The main distinguishable feature between *Ascomycota* and *Basidiomycota* is the fructification of sexual morphs.

Ascus (a sac like or cylindrical structure) which usually contains eight haploid spores (ascospores) at maturity, is the characteristic feature of sexual *Ascomycota*. However, [Kirk et al. \(2008\)](#) regarded that ‘the presence of lamellate hyphal walls with a thin electron-dense outer layer and a relatively thick electron-transparent inner layer also appears diagnostic’. This feature is regarded as a feature to recognize asexual ascomycetous taxa even in the absence of asci. Mainly, there are two morphological groups of asexual fungi based on fructification or conidiomata i.e. coelomycetes (taxa which produce conidia within a cavity lined by either fungal tissue, host tissue, or a combination of both *vide* [Sutton, 1980](#)) and hyphomycetes (which produce conidia from aggregated or separated modified hyphae or conidiogenous cells) borne on the exterior face of substrates and not enclosed by additional fungal or host tissue *vide* ([Sutton, 1980](#)).

[Kendrick \(1989, 2000\)](#) used the term ‘holomorph’ to express whole genome of a taxon. Holomorph can be referred to; 1. only asexual morph (i.e., no sexual morph is reported during the life cycle); 2. only sexual morph (i.e. no asexual morph is reported during the life cycle); and 3. both sexual morph and asexual morph are reported during the life cycle (in some cases, more than one asexual morphs are reported i.e., synasexual morphs; e.g., *Teratosphaeria* with *Colletogloeopsis* and *Kirramyces* coelomycetous morphs and *Batcheloromyces*-like hyphomycetous morph). Third circumstance is called as “pleomorphism” and [Saccardo \(1904\)](#) introduced Dual Nomenclature System of Fungi to name these genera.

In traditional mycology, links between sexual and asexual morphs of pleomorphic genera were established mainly based on co-occurrence of different morphs on same host material and culture-based methods (i.e. asexual morph is produced in the cultures of sexual morph). In modern taxonomy, links are being established mainly on culture-based methods and DNA sequence analyses. Recent taxonomic studies encourage to provide morphological characteristics (i.e. based on holotype), cultures and DNA sequences (i.e., from ex-type cultures) and asexual or sexual morph from cultures or from DNA sequence analyses, when introduces a new taxon.

Life Modes and Habitats

The members of *Ascomycota* are diverse and occur in different ecosystems. Some of these habitats show extreme environmental conditions such as high water salinity (e.g., saline lakes), low light (e.g., fungi in caves), and low nutrition and organic materials (e.g., rock inhabiting fungi). A large number of species have been reported from dry and cold deserts in the Antarctic or highest mountain peaks worldwide ([Selbmann et al., 2005, 2015](#); [Egidi et al., 2014](#)), Arctic glaciers ([Perini et al., 2019](#)), geothermal and humid soils in volcanic areas ([Connell and Staudigel, 2013](#)), acid mine drainages with sulfuric acid ([Baker et al., 2004](#); [Selbmann](#)

et al., 2008) or highly alkaline sites (Rojas *et al.*, 2008). Moreover, some species have been reported from deep permafrost soils (Gilichinsky *et al.*, 2007; Zucconi *et al.*, 2012).

Besides extreme environments, ascomycetous taxa are reported in other different ecosystems such as forests, agricultural lands and commercial forests. In these ecosystems, ascomycetous taxa mainly occur as saprobes, symbionts, pathogens, endophytes and epiphytes. Saprobes play a vital role in decomposition of organic materials and recycling of nutrients in ecosystems. Saprobes are reported in different environments such as aquatic (fresh water, marine) or terrestrial. Fungi on algae, salt marsh fungi, marine derived fungi, fungi in deep-sea environments, mangrove and *Pandanus* associated fungi have been extensively studied (Jones *et al.*, 2015).

Pathogenic taxa are important as it directly influences plant health of forest plants, agricultural crops or ornamental plants. Dieback of trees in primary forests and commercial forests are being reported from different countries and it could impact on both esthetic and commercial values (e.g., see Crous *et al.*, 2019 for *Eucalyptus* pathogens and other associated species). Pathogenic and other associated taxa on ornamental plants are also widely reported and essential to study (see Wanasinghe *et al.*, 2018 for fungi on *Rosa*). However, some studies suggest that these taxa play an important role in regulation of species in the natural ecosystem (Hantsch *et al.*, 2014).

Some fungi are reported as pre-harvest and post-harvest pathogens on agricultural crops. Both types of pathogens are widely studied based on DNA sequences based phylogenetic analyses which provide precise species identification (see Hyde *et al.*, 2014). Several studies showed that these pathogenic species have been reported as species complexes thus identification based on molecular tool is essential (e.g., *Colletotrichum gloeosporioides* fide Weir *et al.*, 2012; *Colletotrichum acutatum* fide Damm *et al.*, 2012a; *Colletotrichum boninense* fide Damm *et al.*, 2012b; *Colletotrichum destructivum* fide Damm *et al.*, 2014).

Epiphytic fungi, which live on leaf or other plant material are also an important group which were mostly reported as sooty molds. These species exclusively grow on honeydew excreted by sap-feeding insects. Honeydew is rich in nutrients thus provide a suitable micro habitat for over 200 epifoliar fungal species (Chomnunti *et al.*, 2011). Lichenized ascomycetous species are one of the examples for symbiotic taxa. Lücking *et al.* (2017) accepted more than 19,000 lichenized species which represents 27% of known Ascomycota. A large number of studies are being published on taxonomy and classification of lichenized Ascomycota and some major and recent studies are Lücking *et al.* (2017), Divakar *et al.* (2017), and Kraichak *et al.* (2018). Ectomycorrhizal Ascomycota taxa have also been reported as other examples for symbiosis. For example, Spatafora *et al.* (2012), and Leonardi *et al.* (2013) reported *Cenococcum* in *Gloniaceae* (Dothideomycetes) and *Pezizales* taxa respectively.

Among other life modes of environmental fungi, lichenicolous (parasitic on lichens), fungicolous (parasitic on other fungi), and algicolous (parasitic on algae) taxa could be regarded as groups that need more studies. However, studies of taxonomy and classification of lichenicolous taxa are comparatively higher than other groups (e.g., Diederich *et al.*, 2018).

Clinically important ascomycetous taxa are also an important group as it directly impacts on human and animal health and other disciplines such as animal husbandry, pharmaceutical industry. These taxa could be morphologically simple taxa (yeasts) or very complex taxa (filamentous fungi).

Species Number

Predicting the number of species in Kingdom Fungi has been a controversial topic for decades and different opinions continue to be expressed based on different approaches such as host-fungi ratio, including modern methods such as next generation sequencing and environmental sequencing (e.g., Blackwell, 2011; Tedersoo *et al.*, 2014; Hawksworth and Lücking, 2017; Wu *et al.*, 2019; Hyde *et al.*, 2020a,b). Hawksworth and Lücking (2017) predicted that the species between 2.2 and 3.8 million of species would be more realistic. However, Wu *et al.* (2019) estimated the number of species as 12 (11.7–13.2) million and this was based on both culture-dependent and -independent survey on same samples.

Currently, number of species of Ascomycota stands at ca. 114,000 (84,000 sexually producing taxa and ca. 30,000 asexually producing taxa) (Wijayawardene *et al.*, 2021). Majority of species which were introduced in every year are ascomycetous (see the series of publications, Botanica Marina series, Fungal Diversity notes, Fungal Biodiversity Profiles, Fungal Systematics and Evolution—New and Interesting Fungi, Mycosphere notes and Fungal Planet). According to recent estimations, the estimated sexually producing species would be around one million (1 M) while the number of asexually producing fungi has been predicted as 570,000 (410,000–730,000) (Wijayawardene *et al.*, 2021). These numbers were based on the host-fungi ratio, as in Hawksworth and Lücking (2017). However, predicted numbers could be less due to synonymy (e.g. some species which have been introduced based on host and morphological characteristics are regarded as synonyms based on DNA based phylogenetic analyses; Groenewald *et al.* (2013) synonymized 45 species of *Cercospora* under several other *Cercospora* species). Nevertheless, there is a high possibility of discovering novel taxa from less studied habitats and life modes, from biodiversity rich areas and existing collections. Moreover, even there could be a large number of undiscovered species from well-studied environments such as fresh water and marine.

Attempts of Higher-Level Classification of Ascomycota

Higher level classification is the most challenged topics as ‘it always been contentious and prone to subjectivity’ (Hyde *et al.*, 2017). Nevertheless, attempts of accommodating of species in higher ranks were carried out in several historic studies (e.g. 1.

Table 1 Major studies of *Ascomycota* in the last decade (2010–2020)

Study	Targeted taxonomic group
Hyde <i>et al.</i> , 2014	Class <i>Dothideomycetes</i>
Wijayawardene <i>et al.</i> , 2014	Class <i>Dothideomycetes</i> (nomenclature)
Jaklitsch <i>et al.</i> , 2016	Phylum <i>Ascomycota</i>
Liu <i>et al.</i> , 2017	Class <i>Dothideomycetes</i>
Hongsanan <i>et al.</i> , 2017	Class <i>Sordariomycetes</i>
Wijayawardene <i>et al.</i> , 2018a,b	Phylum <i>Ascomycota</i> (outline, classification)
Ekanayaka <i>et al.</i> , 2019	Class <i>Pezizomycetes</i>
Ekanayaka <i>et al.</i> , 2019	Class <i>Leotiomycetes</i>
Johnston <i>et al.</i> , 2019	Class <i>Leotiomycetes</i>
Hongsanan <i>et al.</i> , 2020a,b	Class <i>Dothideomycetes</i>
Hyde <i>et al.</i> , 2020a,b	Class <i>Sordariomycetes</i>
Wijayawardene <i>et al.</i> , 2020a,b	Kingdom <i>Fungi</i> (outline, classification)

Saccardo (1884) accepted 6 classes of fungi: Schizomycetes, Myxomycetes, Phycomycetes, Ascomycetes, Basidiomycetes, Deuteromycetes; 2. Sparrow (1943) Accepted 9 classes of fungi: Chytridiomycetes, Oomycetes, Ascomycetes, Basidiomycetes). Subsequent studies of higher ranking of Kingdom *Fungi*, broadly accepted the Phylum *Ascomycota* (e.g., Ainsworth, 1966, 1973; Hawksworth *et al.*, 1983) but Ainsworth (1966) accommodated asexual taxa in a separate subdivision, *Deuteromycotina* which comprises three classes, *Coelomycetes*, *Hyphomycetes* and *Aganomyces*. This was accepted in Sutton (1980) who proposed suborders in class *Coelomycetes*. Higher level classification of asexual taxa was not according to the evolutionary relationships but according to the morphological characters; such as conidiomata, conidiogenous cells, conidiogenesis and conidia.

However, since White *et al.* (1990), taxonomists implemented using DNA sequence analyses for species identification and in classification thus, the understanding of higher-level classification has been subjecting to rapid progression. Among numerous studies on higher level classification of *Fungi*, Seif *et al.* (2005), James *et al.* (2007), Liu *et al.* (2006), Steenkamp *et al.* (2006), Hibbett *et al.* (2007) and Tedersoo *et al.* (2018) are some studies which accepted subdivision *Dikarya* which comprises *Ascomycota* and *Basidiomycota*.

The long-running series *Outline of the Ascomycota* (1982–1986) and *Notes on Ascomycete Systematics* (1986–2010) were exceptional attempts which aimed to provide a current awareness system of *Ascomycota*, and provided 5113 notes. This includes the contribution of Hawksworth and Eriksson (1997–2007) and later, Lumbsch and Huhndorf (2010) provided the updated outline. Lumbsch and Huhndorf (2010) included only the sexual genera in their outline. However, at that period, several studies were published with multi-gene phylogenetic analyses and they provided classification of asexual genera as well (e.g., Schoch *et al.*, 2006, 2009; Crous *et al.*, 2009). These works encouraged to provide an incorporated outline of *Ascomycota*, thus Hyde *et al.* (2011) published “Towards incorporating anamorphic fungi in a natural classification – checklist and notes for 2010”. Later, Wijayawardene *et al.* (2021, 2017b) updated this list with taxonomic notes. Nevertheless, during the period of 2010–2020, several important studies were published which address classification of *Ascomycota* (this includes studies which were carried out for different classes as well) (see Table 1). Moreover, Wijayawardene *et al.* (2017a, 2018a) provided notes for genera of *Ascomycota* (including their classification, number of species, and important references since Kirk *et al.*, 2008) and it included both sexually and asexually typified genera.

Jaklitsch *et al.* (2016) and Wijayawardene *et al.* (2018b) provided the outline of *Ascomycota* with asexually typified genera. Wijayawardene *et al.* (2020a, b) provided the outline of kingdom *Fungi* and fungus-like taxa and it included *Ascomycota*. In both studies, Wijayawardene *et al.* (2018b, 2020a, b) followed the classification proposed by Tedersoo *et al.* (2018).

Besides the phylogenetic studies, several studies have presented the evolutionary relationships of major taxonomic ranks of *Ascomycota*. Studies by Prieto and Wedin (2013), Samarakoon *et al.* (2016, 2019), Hongsanan *et al.* (2017), Liu *et al.* (2017) and Kraichak *et al.* (2018) are some examples which proposed higher level classification of different taxa of *Ascomycota*, based on divergence times.

One Fungus, One Name

Kirk *et al.* (2008) defined the nomenclature as; “the allocation of scientific names to units which a systematist considers merit formal recognition”. During last decade of mycology, numerous changes have been occurring in nomenclature of fungi. These changes could be mainly on pleomorphic fungi, i.e. one taxon shows both sexual and asexual morphs during its life cycle. In some cases, it becomes complicated when one taxon shows two or more asexual morphs, i.e., synanamorphs/synasexual morphs. Saccardo (1904) proposed dual nomenclature system of fungi, i.e., providing different names for different morphs of one taxon (which are morphologically distinct). This was accepted by the International Botanical Congress (IBC) in Vienna, Austria (Briquet, 1905), and became Chapter 59 in more recent editions of the International Code of Botanical Nomenclature (ICBN) (Taylor, 2011). As an example, Samuels and Rogers (1986) introduced the genus *Botryohypoxylon* Samuels & J.D. Rogers and its

Table 2 Major studies proposed to update the name changes of pleomorphic *Ascomycota*.

<i>Taxonomic group</i>	<i>Reference</i>
<i>Ascomycota</i>	Rossmann <i>et al.</i> , 2016, Wijayawardene <i>et al.</i> , 2017a,b, 2018a,b
<i>Diaporthales</i>	Rossmann <i>et al.</i> , 2015b
<i>Dothideomycetes</i>	Wijayawardene <i>et al.</i> , 2014, Rossmann <i>et al.</i> , 2015a, Hongsanan <i>et al.</i> , 2020a,b
<i>Leotiomyces</i>	Johnston <i>et al.</i> , 2014
<i>Magnaporthales</i>	Zhang <i>et al.</i> , 2016
<i>Orbiliaceae (Orbiliomycetes)</i>	Baral <i>et al.</i> , 2017, Ekanayaka <i>et al.</i> , 2018
<i>Sordariomycetes</i>	Maharachchikumbura <i>et al.</i> , 2015, 2016, Réblová <i>et al.</i> , 2016, Hyde <i>et al.</i> , 2020b
<i>Xylariales</i>	Wendt <i>et al.</i> , 2018
<i>Xylariomycetidae</i>	Senanayake <i>et al.</i> , 2015
<i>Pezizomycetes</i>	Healy <i>et al.</i> , 2016

Note: Adopted from Wijayawardene, N.N., Hyde, K.D., Anand, G., *et al.*, 2021. Towards incorporating asexually reproducing fungi in the natural classification and notes for pleomorphic genera. *Mycosphere* 12, 238–405.

coelomycetous asexual morph from a culture and named it as *Iledon* Samuels & J.D. Rogers. The link between two morphs is well-established but it is obligated to provide two names for different morphological taxa.

Dual nomenclature system caused confusions in other different disciplines such as plant quarantine and trade in food and fiber, human health, industrial mycology, and plant breeding (Wingfield *et al.*, 2012; Wijayawardene *et al.*, 2014). Moreover, continuation of two different names for one fungus was questioned since holomorph of most of these taxa were revealed by culture-based techniques and DNA based phylogenetic analyses. Hence, dual nomenclature system was ended since 30 July 2011 (McNeill *et al.*, 2012; Hawksworth, 2012).

International Committee on Taxonomy of Fungi (ICTF) appointed sub committees as ‘working groups’ for different fungal groups (such as *Dothideomycetes*, *Leotiomyces* and *Sordariomycetes*) to propose one name for pleomorphic fungi. Hence, nomenclature of pleomorphic, ascomycetous fungi has been changed significantly, and several major studies were published to propose the “adopted name” and “suppressed name” (see Table 2).

Current Status

The most recent classification of *Ascomycota* (as a whole phylum) was provided in Wijayawardene *et al.* (2020a,b). In this study, Wijayawardene *et al.* (2020a,b) followed Tedersoo *et al.* (2018) who provided the higher-level classification of Kingdom *Fungi* based on phylogenies and divergence time estimates. A combined data set of LSU, SSU, RPB1 and RPB2 genes was used in Wijayawardene *et al.* (2020a,b) and it comprises all orders in kingdom *Fungi*.

Bauer *et al.* (2015) introduced the phylum, *Entorrhizomycota* (which comprises *Entorrhiza* the causal agents of galls on roots of Cyperaceae and Juncaceae) and showed it belongs in subkingdom *Dikarya*. Both analyses of Tedersoo *et al.* (2018) and Wijayawardene *et al.* (2020a,b) showed that *Ascomycota* has grouped with *Basidiomycota* and *Entorrhizomycota*. Hence, phylogenetically and evolutionary, *Ascomycota* has a closer relationship with *Basidiomycota* and *Entorrhizomycota*.

Several important studies were published on different classes of *Ascomycota*, including *Dothideomycetes*, *Leotiomyces*, *Sordariomycetes* (Table 1) and provided comprehensive studies on their life modes, distribution and classification.

Orphaned Genera

In traditional morphology-based classification, phenotypic characteristics are important. However, in natural classification, characteristics of sexual fungi are mainly used (such as type of the ascomata- Apothecial, Perithecial and Pseudothecial; number of layers in ascus- unitunicate operculate and inoperculate, proto-tunicate, bitunicate). In this classification system, asexual genera were not included. However, some asexual typified genera were linked with sexual typified genera as both taxa occur on the host at the same time. Thus, provisionally placed them in the natural classification system (e.g., sooty molds). However, currently, taxonomists use DNA sequences to assign the phylogenetic placements of both sexual and asexual genera.

Currently, 1548 asexually typified genera (which comprise ca. 3850 species) have been treated as *Ascomycota* genera *incertae sedis*. This is mainly due to lack of cultures of older species thus lacking DNA sequences. However, studies which focus epitypification and neotypification of older taxa, re-collected older species and carried out morpho-molecular analyses. Hence, it provides precise morphological boundaries, putative cultures, DNA barcodes and phylogenetic placements.

Compare to orphan asexually typified taxa, number of sexually typified orphaned genera are low in number. Apparently, most of the older sexual taxa possess well preserved micro characteristics compare to asexual taxa. Hence, even after a long period of time, taxonomists could observe the holotype or isotypes to accommodate them in modern classification. The structures produced in conidial fungi are delicate and easily deforms. As an example, hyphomycetous taxa produce conidia from a conidiogenous cells

which are not covered by and structure as in sexual fungi or coelomycetous taxa. Thus, it is highly fragile and easy to destroy its important characteristics (such as conidiogenous cells, conidial characteristics- chains, appendages).

Some recent studies suggest to extract DNA from the older herbarium specimens (e.g., [Forin et al., 2018, 2020](#)). This is an interesting attempt since a large number of old species were based only on herbarium materials and cultures were not deposited. Nevertheless, [Forin et al. \(2018\)](#) stated that the ‘ancient herbarium samples have both time and conservation related DNA damages, besides exogenous DNA contamination, that make nucleic acid extraction and amplification challenging’. Hence, we believe that the epitypification should be prioritized first for barcoding older taxa. (epitypification will be discussed in the last section).

Novel Lineages Within the Phylum

Revealing phylogenetic lineages of ascomycetous taxa is being increased by DNA-based phylogenetic analyses. [Wijayawardene et al. \(2021\)](#) highlighted some families with a high number of asexual typified genera such as *Mycosphaerellaceae* (*Capnodiales*, *Dothideomycetes*), *Phaeosphaeriaceae*, *Didymellaceae* (*Pleosporales*, *Dothideomycetes*), *Nectriaceae*, *Stachybotryaceae* (*Hypocreales*, *Sordariomycetes*). Interestingly, most of genera in these particular families have been introduced in the last decade (2010–2020). Polyphasic approach (mainly DNA based molecular techniques and morphological characteristics) was the main tool for species identification, as well to provide a higher-level ranking. Apparently, these families can harbor more taxa, which belong in the same genera or as new genera, in particular families since known taxa show worldwide distribution and are not host specific. As an example, the genus *Allophoma* Qian Chen & L. Cai was introduced by [Chen et al. \(2015\)](#) to accommodate six species (including five new combinations and one new species). Subsequent studies by [Chen et al. \(2017\)](#), [Babaahmadi et al. \(2018\)](#), [Valenzuela-Lopez et al. \(2018\)](#), [Jayasiri et al. \(2019\)](#), [Marin-Felix et al. \(2019\)](#), [Hou et al. \(2020\)](#) and [Yuan et al. \(in prep.\)](#) introduced eight *Allophoma* species.

Besides lineages in known higher-level ranks, several recent studies recognized new phylogenetic lineages of asexual taxa in *Ascomycota*. *Neocelosporiaceae* Crous, *Strelitzianaceae* Crous & M.J. Wingf. and *Cochlearomycetaceae* Crous are three families that have been introduced recently exclusively based on asexual taxa and DNA based phylogenetic analyses were the main tool to recognize them ([Crous et al., 2015, 2017, 2018](#)). Detailed and systematic studies targeting particular hosts and geographic regions (from which known taxa are reported) may reveal numerous new taxa in these families.

However, phylogenetic and evolutionary stability of monospecific families and higher-ranks have to be considered prior to introduce them. Nevertheless, in a “conservation point of view, these families are important as they may represent species-rich relic taxa from early lineages that hold a unique gene pool” ([Chethana et al., 2020](#)). It would be foreseeable to discover new taxa in such new and less studied lineages, such as those in *Basidiomycota* that have been less studied compared to *Ascomycota* ([Wijayawardene et al., 2021](#)).

Future Perspectives and Conclusion

Current studies of *Ascomycota* could be recognized in several disciplines such as taxonomy (based on morphology, DNA sequence, secondary metabolites), industrial applications, ecological studies and pathological studies. Among these, taxonomic studies are important since its outputs directly impact on other disciplines. For an example, precise species identification of pathogens is a key factor in agriculture, import-export industry, plant breeding. Instead, DNA based techniques impact on species identification, linking sexual-asexual morphs, phylogenetic placements thus it is essential to integrate all these changes.

a. Continuously updating web-based classification system

During preparation of [Wijayawardene et al. \(2017a,b, 2018a,b, 2020a,b\)](#), these authors recognized two crucial limitations while compiling the outline.

- (1) There can be disagreement and dispute among different research groups on taxonomic boundaries of genera and higher taxa.
- (2) As phylogenetic data are still being collected at a very high pace and increasingly being used in taxonomy, there is the necessity of constantly updating classification schemes and incorporate new findings.

Hence, the classification of whole kingdom is provided in see “Relevant Websites Section” ([Wijayawardene et al., 2020a,b](#)) which has been targeted to update continuously. Additionally, several other important web sites have been launched recently (e.g., [onestopshopfungi.org](#) (see “Relevant Websites Section”), [dothideomycetes.org](#) (“See Relevant Websites Section”), [fungalgenera.org](#) (“See Relevant Websites Section”), [facesoffungi.org](#) (“See Relevant Websites Section”), [theyeasts.org](#) (see “Relevant Websites Section”) provide information on pathogenic genera, *Dothideomycetes* genera, typification data, descriptions of species and other taxonomic ranks, and yeast genera, respectively ([Jayasiri et al., 2015](#); [Jayawardena et al., 2019](#); [Monkai et al., 2019](#); [Pem et al., 2019](#)). Doctor Fungus (see “Relevant Websites Section”), Mycology Online (see “Relevant Websites Section”), and the *Aspergillus* and *Aspergillois* Website (see “Relevant Websites Section”) are dedicated websites for clinically important fungi. The website “See Relevant Websites Section” deals with the latest taxonomy of marine fungi ([Jones et al., 2019](#)).

(1) Epitypification, culture depositing and barcoding

It is essential to designate a new type “in cases where the type material of a species is an illustration, is lost, or is in poor condition” (Ariyawansa *et al.*, 2014). When an old specimen is not in good condition, an epitype (i.e., a specimen or illustration selected to serve as an interpretative type when the holotype, lectotype, or previously designated neotype, or all original material associated with a validly published name, is demonstrably ambiguous and cannot be critically identified for purposes of the precise application of the name of a taxon. When an epitype is designated, the holotype, lectotype, or neotype that the epitype supports must be explicitly cited *fide* McNeill *et al.*, 2012) can be designated and the new material can be used as the material for precise morphological identification, isolation and obtain living cultures and extract DNA. Ariyawansa *et al.* (2014) discussed the steps and procedures of designating an epitype.

A culture collection is “a library containing examples of the genotypic and phenotypic diversity of plant pathogens” (Abd-El salam *et al.*, 2010). Ariyawansa *et al.* (2014) strongly suggested “to deposit at least two collections of fungus cultures, one should be a public culture collection”. Currently, most of the publications included taxa with culture details while some studies used dried cultures as herbarium material.

Recent molecular assays used for identification of common pathogens and other fungi. Different gene regions have been using in different studies to precise identification and Schoch *et al.* (2012) regarded ITS gene region as the universal barcode. However, the other gene regions, including protein genes are widely used for species identification and to confirm phylogenetic placement. During the epitypification of old species, it is essential to recognize the best gene regions for the particular species to serve as its barcoding genes.

(2) Looking for missing taxa

Current species number of kingdom *Fungi* stands at ca. 150,000 and approximately, 110,000 species belong in *Ascomycota*. However, this number comprises synonyms (e.g species introduced based on host) thus, number could be lower. Nevertheless, still a large number of species are regarded as “missing species”. Resolving species complexes which comprises cryptic species, and extensive studies in existing and reference collections, studying habitats and life modes which have been less-studied, and biodiversity rich areas will be helpful to discover missing species (Hawksworth and Lücking, 2017).

Isolation and cultivation of microbes and their characterization through direct observation investigations of the diversity and functioning of microbial communities have been based on of distinct morphologies. However, recent studies questioned whether we can discover all the missing taxa. Metagenomics emerges as the study of genetic material recovered directly from environmental samples in an untargeted way (Riesenfeld *et al.*, 2004). Based on cutting-edge sequencing techniques and computational methods for genome assembly, nowadays, it is possible to identify full (or nearly full) microbial genomes directly from environmental samples. By obtaining these “uncultured genome sequences”, the breadth of our understanding of microbial ecology is undoubtedly enhanced. Moreover, unculturable and missing taxa might be thoroughly characterized at molecular level. Even if some characteristics might be inferred from genome sequence, the lack of living cultures limits the full taxonomical description (e.g., morphologically, physiologically, biochemically) of the microbes corresponding to these “uncultured genome sequences”. This genome-guided approach could definitely enhance current isolation and cultivation strategies for these “unculturable” taxa.

(3) Fossil genera and placing them in modern classification

Recent outline of fungi, Wijayawardene *et al.* (2020a,b) included the fossil taxa and provided their classification. As the second major step, Saxena *et al.* (2021) incorporated all the fossil species into one draft. However, apparently, a large number of taxa are related to modern Ascomycetous genera thus we suggest that it is worthy to accommodate these genera in modern genera.

Acknowledgments

This work was supported by the Key Laboratory of Yunnan Province Universities of the Diversity and Ecological Adaptive Evolution for Animals and Plants on the Yun-Gui Plateau, the National Natural Science Foundation of China (No. NSFC 31950410558, NSFC 31760013, 31260087, 31460561), and the Scientific Research Foundation of Yunnan Provincial Department of Education (2017ZZX186). Introduction

Fungi are a diverse group of eukaryotic organisms that have been recovered from numerous habitats (Hyde *et al.*, 2020). The *Ascomycota* is the largest phylum of fungi encompassing over 6500 genera with over 80,000 species (Wijayawardene *et al.*, 2017). The phylum includes yeasts, filamentous fungi and lichenized fungi which occupies a variety of niches. The ascomycetes are of great economic importance as saprobes, pathogens, producers of antibiotics, as control of insect pests and several other industrial applications (Hyde *et al.*, 2019). Fungi can reproduce either sexually or asexually. Sexual reproduction is considered the most prevalent form of reproduction in eukaryotes (Seidl *et al.*, 2009). Sexual reproduction is vital for the long-term population persistence of most eukaryotes, but it requires more time and energy (Heitman *et al.*, 2007). In some cases, sexual reproduction can be less efficient compared to asexual reproduction as it depends on the production of several chemicals for the recognition and attraction of a compatible mate (Martin *et al.*, 2013).

During asexual reproducing, fungi produce genetically identical spores and it is characterized by mitotic divisions which result in the formation of endospores or conidia. During sexual reproduction in fungi, haploid cells fuse during plasmogamy, which is followed by the fusion of two haploid nuclei during karyogamy (Wallen and Perlin, 2018). The diploid cells then undergo meiosis to produce haploid cells. It is hypothesized that sexual reproduction occurs as a means of DNA repair due to exposure to adverse environmental conditions (Neiman, 2011). Sexual reproduction also occurs as a means to generate new combinations of alleles thus increasing the fitness of the offspring (Rodenburg *et al.*, 2018).

In *Ascomycota*, the sexually produced ascospores are contained in the asci, which are enclosed in an aggregation of hyphae called the ascomata or ascocarps (Meyer and Luttrell, 1986). The ascoma can therefore be described as a multicellular structure that protects the ascospores. The ascospores of unicellular fungi such as yeasts are not enclosed in ascomata. The development of ascomata is a complex process which requires the expression of specific genes and it can be affected by environmental factors.

In this chapter, we provide a description of the morphology of ascomata and an overview of the development of ascomata. We also discuss factors that can control the development of ascomata and provide examples of model organisms which have been vital in the study of ascomata formation.

Morphology of Ascomata

The ascomata are usually composed of the peridium, the asci and the hamathecium (Eriksson, 2001). The asci can form a distinct, inner layer in the ascoma called the hymenium (Eriksson, 2001). The different ascomata morphologies were previously used to classify filamentous fungi, but this classification was not fully supported as monophyletic by molecular-based analyzes (Schoch *et al.*, 2009; Ebersberger *et al.*, 2012). There are four main types of ascomata, apothecia, cleistothecia, perithecia and pseudothecia. Apothecia are open to cup-shaped ascomata that have a hymenium which is directly exposed to the environment. The hymenium in apothecia can sometimes be covered by a thin sterile tissue during the early stage whereby the asci and hamathecium are arranged in a palisade-like hymenium (Eriksson, 2001). Apothecia can be found in species including *Ascobolus immersus* and *Pyronema confluens* (Fischer *et al.*, 2004).

Cleistothecia are closed, spherical ascomata that open in a variety of ways to disperse the mature spores as a result of the peridium dissolving or cracking gradually or explosively (Eriksson, 2001). Several *Aspergillus* and *Penicillium* species produce cleistothecia such as *A. fumigatus*, *A. nidulans* and *P. chrysogenum* (Sohn and Yoon, 2002; Yu *et al.*, 2018). Perithecia are ascomata with flask-shaped structures with a preformed opening, the ostiole for spore release. Sterile hyphae can sometimes surround the perithecial cavity that encloses the hymenium. Perithecia can be found in species including *Neurospora crassa* and *Sordaria clematidis* (Bistis *et al.*, 2003; Phukhamsakda *et al.*, 2020). Pseudothecia are spherical ascomata that contain loculi. Spores are released through openings which are formed from the lysis of the peridium. Pseudothecia can usually be found in several families in *Dothideomycetes* including *Anastomitrabeculiaceae*, *Delitschiaceae* and *Didymellaceae* (Barr, 2000; de Gruyter *et al.*, 2009; Hongsanan *et al.*, 2020; Bhunjun *et al.*, 2021).

Ascomata Development in Model Systems

Ascomata development has been studied in several ascomycetous species whose sexual life cycle can be induced in the laboratory. Ascomata are highly complex structures that contain different tissues which protect the internal structures with the envelope and

the dikaryotic hyphae forming part of the integrated structure (Wilson *et al.*, 2019). Ascomata are formed as a result of fertilization which occurs through several highly regulated development processes. Sexual reproduction in fungi involves the differentiation of mating structures and the recognition of mating partners. The mating identity is genetically defined by the mating-type loci (MAT) whereby the identity and mating compatibility is established by the production of sexual pheromones (Jones and Bennett, 2011).

Ascomata formation begins with fertilization which depends on whether the species is genetically self-compatible (homothallic) or genetically self-incompatible (heterothallic) (Wilken *et al.*, 2012). The mating system in heterothallic fungi only occurs between compatible partners with MAT locus which encompasses alternative idiomorphic alleles located at the same genomic position but with different sequence information. The mating system in homothallic fungi is also controlled by the MAT locus, but in these fungi, the locus has adopted an arrangement which allows sexual reproduction of genetically identical cells. Fruiting body development also depends on several other factors including coordinated enzyme activity in cell wall biogenesis and also depends on genes responsible for the cytoskeleton (Peraza-Reyes and Malagnac, 2016).

The model organism *Neurospora crassa* is a heterothallic filamentous species of the *Sordariaceae*. *Neurospora crassa* has been found in tropical, subtropical and temperate regions as well as on the surface of fire-scorched vegetation due to its ability to metabolize cellulose and because the heat activates the sexual spores (Ruger-Herreros and Corrochano, 2020). The fruiting body of *N. crassa* is very complex as it can have up to 15 different cell types (Bistis *et al.*, 2003). It has a complex sexual life cycle as it possesses two alternative versions of the MAT loci (MAT1-1 and MAT1-2) and both versions can produce the male gametangia (macro- and microconidia) and the female gametangia (ascogonia) (Debuchy *et al.*, 2014; Kück *et al.*, 2016). Sexual reproduction starts with the fusion of compatible gametes. The male gametangia, also known as the antheridia or spermatia are small conidia-like cells that are formed directly on the mycelium whereas the ascogonia are large coiled cells. In *N. crassa*, the ascogonia mature into preformed fruiting bodies, called protoperithecia after two to three days while surrounded by protective layers of vegetative hyphae. The maturation of ascogonia to protoperithecia is dependent on metabolic regulation as it only occurs at low nitrogen concentrations. The mature ascogonia await fertilization in this protective envelope and the protoperithecia produce specialized hyphae called trichogynes which fuse with the male haploid nucleus leading to the induction of the dikaryotic phase. After fertilization, the fusion of the two haploid nuclei does not proceed immediately, but instead the male and female haploid nuclei are formed, which migrate into called croziers which are hook-shaped ascogenous hyphae. These dikaryotic tissues grow within the haploid envelope where they obtain nutritional resources. The fruiting bodies also contain sterile hyphae and paraphyses which are usually hyphae from the female parental strain. The dikaryotic cells formed by heterothallic species result in a genetically compatible haploid nucleus of each mating type, which can consequently undergo karyogamy to form a diploid cell. After several rounds of conjugated divisions, the diploid cell undergoes meiosis, resulting in the development of asci which starts with the formation of ascogenous hyphae and crozier cells. There is a post-meiotic mitosis stage prior to spore formation which results in the formation of eight spored asci. A heat shock is required to induce ascospore germination in *N. crassa* (Noguchi *et al.*, 2007).

Podospora anserina is a heterothallic *Sordariomycetes*, which has a similar sexual development pattern to *N. crassa* (Silar, 2013; Lehr *et al.*, 2014). The ascogonia of *P. anserina* also mature into preformed fruiting bodies while surrounded by protective layers of vegetative hyphae. It also has two mating-type strains, but there are some differences as *Podospora anserina* does not generate macroconidia which can germinate under specific environmental conditions. *Podospora anserina* has four spored asci due to specific nuclear mechanisms. Following the post-meiotic mitosis stage, the spore-wall formation contains two genetically distinct nuclei, each with one type of mating strain. The spermatia and the ascogonia in *P. anserina* start to differentiate after growing for three days at an optimal temperature of 27°C. The perithecia mature four days after fertilization whereas the peridium neck and ostiole are formed two days after fertilization. Once fully mature, the fruiting body continuously releases hundreds of ascospores for five days. The perithecia of *P. anserina* can enlarge over 100-fold during the development process, which requires a significant amount of nutrient. Therefore, the nutrient availability of the colony and the ability to use appropriate signaling pathways to detect the nutrient status is vital for sexual development (Wilson *et al.*, 2019). In *P. anserina*, it is hypothesized that the developing peridium sends a signal to the surrounding mycelium through diffusible reactive oxygen species as a result of the PaNox1 NADPH oxidase enzyme and mediated by the Pezizomycotina-specific protein IDC1 (Jamet-Vienmy *et al.*, 2007; Nguyen *et al.*, 2018). These proteins are important for the development of the perithecium envelope. The signal is then transduced by the PaMpk1 MAP kinase cascade which results in the mobilization of nutrients for the development of the ascomata (Kicka and Silar, 2004; Lalucque *et al.*, 2017).

Sordaria macrospora is a filamentous ascomycete from *Sordariales*. It has been used extensively as a model system to study ascomata development (Teichert *et al.*, 2020). *Sordaria macrospora* has the advantage of having a short life cycle, which takes only seven days to complete in laboratory conditions. This fungus has a similar life cycle to *N. crassa* and *P. anserina*, but *S. macrospora* differ as it is homothallic and a single strain can complete the life cycle without a mating partner. *Sordaria macrospora* produces only ascospores as it lacks any vegetative spores. Unlike *N. crassa*, the ascospores of *S. macrospora* do not require a heat shock or a resting period for germination (Teichert *et al.*, 2020). The sexual cycle contributes to the propagation of *S. macrospora* and it starts with the formation of ascogonia but the mechanism leading to the formation of the dikaryotic hyphae is poorly understood. Karyogamy of two nuclei in the crozier cells is followed by meiosis to produce ascospores. Meiosis is then followed by postmeiotic mitosis which results in an ascus with eight ascospores (Teichert *et al.*, 2020). Recombination can occur between two strains of homothallic species such as *S. macrospora*. Therefore, they can be used for conventional genetic analysis which usually uses strains of compatible partners from heterothallic species with opposite mating types such as *N. crassa* (Teichert *et al.*, 2020).

Aspergillus nidulans is another model organism which has been used to study genetic recombination and ascomata development (Braus *et al.*, 2002). It is a homothallic ascomycete from *Eurotiomycetes* which is hypothesized to have a similar life cycle to *S. macrospora*. This species has no proper gametes and self-fertilization results in the formation of a small coiled lump of cells

similar to ascogonia. These calls are surrounded by a loose layer of growing hyphae which develop into the cleistothecium envelope. The developing fruiting body of *A. nidulans* is surrounded by a second layer of thick-walled multinucleate hülle cells which protects and provides nutrients to the developing fruiting body. Following karyogamy and meiotic division, the dikaryotic ascogenous hyphae can produce up to 1000 ascospores per cleistothecium (Sohn and Yoon, 2002). All *Aspergillus* species were hypothesized to propagate asexually, but several heterothallic *Aspergillus* species can undergo sexual reproduction including *A. flavus*, *A. fumigatus* and *A. parasiticus* (Kück and Pöggeler, 2009; Dyer and O’Gorman, 2011; Dyer and Kueck, 2017). The sexual lifecycle allows the application of conventional genetic analysis via crossing to investigate fruiting-body development.

Several other model species have recently been used to investigate the development of fruiting bodies including *Botrytis*, *Trichoderma* and *Penicillium* species. *Botrytis cinerea* is a plant pathogen with a wide range of host. It is a member of the *Helotiales* and it is an important model in molecular plant pathology. *Botrytis cinerea* is heterothallic and it possesses two alternative versions of the MAT loci: MAT1–1 and MAT1–2 (Amselem *et al.*, 2011). Asexual reproduction in *B. cinerea* is influenced by light as microconidia are released in the presence of light whereas sclerotia are released in the absence of light. During the early stages of development, the fruiting body of *B. cinerea* grow towards the light source (Schumacher, 2017). The limitation of using *B. cinerea* as a model organism is that it is time-consuming to induce its sexual life cycle which can take up to six months to develop a mature fruiting body (Farettra and Antonacci, 1987).

Trichoderma reesei is one of the most important cellulase and hemi-cellulase producers (Seidl *et al.*, 2009). It is an important model that has been used to study the development of the ascomata and the regulation of plant cell wall degrading enzymes. *Trichoderma* species have been considered to be largely asexual, but crossing experiments of the industrial strain have led to fertilized ascomata and the production of mature ascospores. The industrial strain however is unable to produce female reproductive structures and is therefore female sterile (Seidl *et al.*, 2009). Female sterility in this strain is hypothesized to be due to the collection being maintained in laboratory conditions for a long time. It could also be due to an accumulation of mutations during vegetative reproduction resulting in a loss of meiosis which produces female sterile mutants (Leslie and Klein, 1996). *Penicillium chrysogenum* is a model organism with major biotechnological importance and it has been considered to be asexual for over 100 years (Böhm *et al.*, 2013). Most industrial filamentous fungi lack a sexual cycle, which is problematic for crossing experiments to generate strains with novel combinations. Böhm *et al.* (2013) provided evidence for the presence of a heterothallic sexual cycle in *P. chrysogenum* and Ropars *et al.* (2014) induced the sexual cycle in *P. roqueforti*.

Factors Affecting the Development of Ascomata

The development of ascomata can be affected by several environmental factors including light, nutrients and atmospheric conditions. Each fungus responds differently to environmental factors. Light can influence the phototropic growth of reproductive structures and it can also affect gene expression and secondary metabolism (Casas-Flores and Herrera-Estrella, 2016). In *Aspergillus glaucus* and *A. nidulans*, asexual reproduction usually occurs in the presence of light and sexual reproduction usually occurs in the absence of light (Geiser, 2009; Dyer and O’Gorman, 2012; Debuchy *et al.*, 2014). There are several ascomycetes whose ascomata formation, phototropism of perithecial necks and ascospore discharge are light-dependent (Moore-Landecker, 1992). The apothecia formation in *Ascobolus magnificus*, *Pyronema omphalodes* (= *Pyronema confluens*) and *P. domesticum* are light-dependent (Traeger *et al.*, 2013; Casas-Flores and Herrera-Estrella, 2016). In the model organism *Trichoderma reesei*, stromata formation occurs only in the presence of light (Seidl *et al.*, 2009). In *Botrytis cinerea*, the formation of sclerotia which serves as survival structures and female mating partners is inhibited in the presence of light (Schumacher, 2017). The positioning of the perithecial neck in species such as *Neurospora crassa* is dependent on the presence of light and the action of the nucleoside diphosphate kinase (NDK-1) (Harding and Melles, 1983; Ogura *et al.*, 2001).

The development of ascomata is also influenced by the availability of nutrients. Fruiting bodies are usually generated when there are limited nutrients with the exception of fungi such as *A. nidulans* and *S. macrospora* (Dyer and O’Gorman, 2012; Wilson *et al.*, 2019). The development of ascomata can also be affected by temperature. Mycelium growth can usually occur at a range of temperature, but ascomata development requires a restricted range. For example, ascomata formation in *Fusarium solani* (*Nectria haematococca*) usually occurs between 21°C and 24°C (Moore-Landecker, 1992). Sub-optimum temperature can result in sterile ascomata. For example, ascomata formation in *Pyronema domesticum* occurs at the optimum temperature of 20°C, but sterile ascomata without ascogenous hyphae and asci are produced at 30°C (Moore-Landecker, 1992). Another factor that influences the formation of ascomata is the ratio of carbon and nitrogen (Moore-Landecker, 1992). Ascomata formation in some fungi can also be dependent on the availability of additional nutrients such as vitamins or amino acids. For example, ascomata formation in *Sordaria fimicola* and *S. macrospora* is dependent on biotin (Barnett and Lilly, 1947). The completion of the sexual life cycle of *S. macrospora* is dependent on arginine which is vital for several biological processes (Molowitz *et al.*, 1976). Ascomata formation in some species can be increased in the laboratory by adding fatty acids to the medium. Ascomata formation in *Ophiostoma ulmi* (*Ceratocystis ulmi*) and *Fusarium solani* (*Nectria haematococca*) can be increased by adding linoleic acid whereas oleate and linoleate can be used to increase ascomata formation in *N. crassa* (Marshall *et al.*, 1982; Dyer, Ingram and Johnstone, 1993). The development of ascomata in some fungi can also be influenced by the availability of carbon dioxide. Ascomata formation in *Aspergillus nidulans* is promoted during increased pressure of carbon dioxide whereas limitation of carbon dioxide promotes asexual sporulation (Han *et al.*, 2003; Dyer and O’Gorman, 2012). Ascomata formation in *A. nidulans* is also promoted during high concentration of carbon sources such as lactose, galactose and glycerol as well as during high concentration of organic nitrogen sources

such as casein hydrolysate and glycine whereas their limited availability promotes asexual development (Han *et al.*, 2003). High concentration of certain ions such as potassium, sodium or magnesium promotes asexual development in *A. nidulans* (Markina-Iñarrairaegui *et al.*, 2020).

There are several signaling pathways that detect nutrient status during ascomata development. Nutrient sensing usually occurs through plasma membrane proteins especially the G-protein-coupled receptors which are especially important for regression of sexual development (van Dijck *et al.*, 2017). *Fusarium graminearum* strains which have proton-coupled dipeptide transporters formed more ascomata compared to strains lacking the transporters (Droce *et al.*, 2017). Signaling proteins play an important role in nutrient utilization and ascomata formation. The sucrose non-fermenting 1 (*SNF1*) protein kinase is important in the transcription of glucose-repressible genes in response to glucose starvation, thus enabling the utilization of alternative carbon sources. *Fusarium graminearum* strains lacking *SNF1* formed fewer ascomata which matured more slowly and formed asci with abnormally shaped ascospores (Lee *et al.*, 2009). The protein kinase *IME2* (Inducer of meiosis 2) is involved in the regulation of several cellular processes including ascospore formation and ascomata formation (Xie *et al.*, 2020). The first identification of the kinase *IME2* was as a gene which is involved in meiotic control in *Saccharomyces cerevisiae* (Smith and Mitchell, 1989; Yoshida *et al.*, 1990). In *N. crassa*, the *IME2* downregulates the development of the protoperithecia in the presence of nitrogen (Irniger, 2011). Homologs of *IME2* have also been identified which are involved in the repression of fruiting-body formation in response to environmental factors such as limited light and nutrient availability (Irniger, 2011). The protein kinase *Crk1* which is a homolog of *IME2*, is responsible for morphogenesis, mating and virulence in *Ustilago maydis* (Garrido *et al.*, 2004). As the stromata formation of *T. reesei* occurs only in the presence of light, photoreceptors such as *BLR1* and *BLR2* play an important role in the pheromone system and fruiting body development (Seibel *et al.*, 2012). Another important photoreceptor is the *ENV1* (*ENVOY1*) which is crucial for the proper regulation of the sexual development in *T. reesei* unlike *BLR1* and *BLR2* (Bazafkan *et al.*, 2017). The photoreceptor *ENV1* and *PhLP1* (class I phosphatase-like protein) act together as regulators of heterotrimeric G-protein signaling and they are involved in the proper regulation of light responsiveness during long-term exposure. Vacuolar H⁺-ATPases (V-ATPases) are proton pumps which are important for lysosomal and endosomal functions (Parra *et al.*, 2014). Mutation in the *vma-1* gene which encodes for subunits of V-ATPases result in female-sterile *N. crassa* strains which can only grow in an acidic medium (Bowman *et al.*, 2000). The *PHOA* cyclin-dependent kinase (CDK) modulates differentiation of asexual and sexual cells in response to environmental conditions such as pH and phosphorus concentration in *A. nidulans* (Dou *et al.*, 2003).

The formation of ascomata is also dependent on endogenous substances such as primary and secondary metabolites as well as pheromones which are vital for the completion of the cycle. Mutations in the genes for primary metabolism can interfere with ascomata formation. In *A. nidulans*, loss of the *hisB* gene (histidine biosynthesis) and the *trpB* gene (tryptophan synthase-encoding) inhibit the formation of ascomata during low concentration of histidine and tryptophan (Eckert *et al.*, 2000; Busch *et al.*, 2001). Ascomata formation in *A. nidulans* can be induced by oleic acid, but this induction is prohibited in strains lacking *PexF* genes (peroxin) (Hynes *et al.*, 2008). In *Fusarium graminearum*, loss of the *ICL1* gene (Glyoxylate cycle) which is essential for the utilization of carbon sources, results in defects during ascomata formation (Lee *et al.*, 2009). Nitric oxide can also influence the formation of ascomata formation as it is important in morphogenesis and reproduction (Cánovas *et al.*, 2016). In *A. nidulans*, the concentration of nitric oxide increases sharply after switching from vegetative growth to sexual or asexual growth (Cánovas *et al.*, 2016). Nitric oxide could therefore represent a signal of development in filamentous fungi (Zhao *et al.*, 2020). Ascomata formation can be promoted by citric acid for example in *Aspergillus glaucus* and the loss of the *citA* gene (citrate synthase) inhibits meiosis, which results in ascomata without ascospores (Cai *et al.*, 2010; Murray and Hynes, 2010).

Secondary metabolites can also influence ascomata development. Pigmented ascomata or ascospores in ascomycetes is usually due to the presence of polyketide melanin (Coppin and Silar, 2007). It is hypothesized that the pigments protect ascospores from environmental factors and it also provides structural support to the ascomata (Langfelder *et al.*, 2003). The polyketide synthase (*PKS*) gene is vital in the formation of structures during sexual reproduction and mutation of the gene results in female sterility in *Neurospora crassa* (Noar *et al.*, 2019). The loss of *PKS-4* gene in *S. macrospora* inhibits the formations of ascomata whereas expression of the gene results in large, abnormally shaped ascomata (Schindler and Nowrousian, 2014). Another important class of secondary metabolites are the oxylipins which have important signaling roles in mammals, plants and fungi (Naranjo-Ortiz and Gabaldón, 2020). Oxylipins are vital in several processes including morphological switches and secondary metabolism, but their role in the sexual cycle of ascomycetes remains unclear (Brodhun and Feussner, 2011; Naranjo-Ortiz and Gabaldón, 2020). In *Aspergillus nidulans*, asexual reproduction occurs in the presence of light and sexual reproduction occurs in the absence of light. The *veA* gene (Velvet complex subunit A) is important to maintain this light-dependent balance and the loss of *veA* gene inhibits the formation of ascomata (Mooney and Yager, 1990; Kim *et al.*, 2002). In *T. reesei*, the *VEL1* (*veA* orthologue) The *csnD* gene (COP9 signalosome complex) is also another important regulator of the light-dependent balance similar to the *veA* gene, but it is also important for correct sexual development (Dyer and O'Gorman, 2012).

During sexual reproduction, heterothallic ascomycetes produce trichogynes which fuse with the male haploid nucleus leading to the dikaryotic phase. In *Saccharomyces cerevisiae*, diffusible peptide pheromones activate the cognate G-protein-coupled receptors (GPCRs) at the surface, which activates signals that are responsible for chemoattraction and fusion of the male and female cells (Alvaro and Thormer, 2016; Bennett and Turgeon, 2017). In *N. crassa*, diffusible peptide pheromones are responsible for the directional growth of trichogynes towards the male cells, but the directional growth is inhibited in the presence of mutations at the mating-type locus of the male cells. This suggests that these locus control the regulation of pheromones production (Kim and Borkovich, 2006). In heterothallic ascomycetes, pheromones and their receptors are involved in the recognition of opposite mating types (Martin *et al.*, 2011). In heterothallic and homothallic fungi, pheromones and their receptors are involved in the

regulation of post-fertilization events (Jones and Bennett, 2011). In heterothallic ascomycetes, deletion of pheromone genes results in male sterility whereas in homothallic ascomycetes, it does not impair vegetative growth or fruiting-body development (Mayrhofer *et al.*, 2006; Klix *et al.*, 2010; Martin *et al.*, 2011). Pheromone precursor genes are highly expressed under optimum conditions for sexual reproduction in the heterothallic *N. crassa* and the homothallic *P. anserina* (Coppin *et al.*, 2005). This suggests that pheromones and their receptors can adapt to different lifestyles and they can be involved in more complex processes.

Regulatory Networks Involved in the Development of Ascomata

The development of ascomata is a complex process which is controlled by several systems including signaling pathways (Wilson *et al.*, 2019). These signals are important for several processes including mate recognition, induction of ascomata formation and ascomata formation. In *N. crassa*, the mitogen-activated protein kinase (MAPK) cascades are important for sexual development (Lamb *et al.*, 2012). These are highly conserved signaling transduction modules that transmit signals from the cell surface to the nuclei. In ascomycetes, three different MAPK are present which control cell wall integrity (CWI), pheromone signaling (PR) and osmotic stress (HOG) (Manfiolli *et al.*, 2019). The CWI pathway is important in ascomata development and the pathway is mainly activated by cell wall stress (Levin, 2005). Strains lacking the kinases of the CWI pathway are unable to produce mature ascomata and it had an impact on the cell wall integrity (Sanz *et al.*, 2018). The PR pathway is important for early colony development, cell fusion and cell to cell communication (Jonkers *et al.*, 2014). The HOG pathway is vital for adaptation to stress conditions (Rodríguez-Pena *et al.*, 2010). The HOG pathway is activated by a range of stressors including oxidative stress, acid stress, temperature stress and heat stress (Winkler *et al.*, 2002; Bilsland *et al.*, 2004; Mollapour and Piper, 2006; Panadero *et al.*, 2006).

The striatin-interacting phosphatase and kinase (STRIPAK) complex was first discovered in humans and homologous complexes have also been identified in several eukaryotes (Ribeiro *et al.*, 2010; Hwang and Pallas, 2014). In fungi, the STRIPAK regulates ascomata development, vegetative growth, hyphal fusion, asexual development as well as pathogenic and symbiotic interactions with the host (Bloemendal *et al.*, 2012; Märker *et al.*, 2020). The reactive oxygen species produced by NADPH oxidases act as important regulator of cellular processes in cell differentiation and development (Aguirre *et al.*, 2005). The NADPH oxidases are important regulators of ascomata formation, hyphal fusion and ascospore germination (Malagnac *et al.*, 2004). The COP9 signalosome (CSN) complex is conserved from fungi to human and it is involved in post-translational processes, including protein ubiquitination and phosphorylation (Braus *et al.*, 2010). Strains lacking *c sn* gene show defects in sexual fruiting-body development, despite initiating sexual development (Busch *et al.*, 2007).

Concluding Remarks

Fruiting body formation is a complex process and filamentous ascomycetes can generate several different types of ascomata with up to 15 different cell types. Filamentous ascomycetes serve as an important model to study various important processes including the development of ascomata. The complexity of ascomata formation is enhanced due to the effect of different environmental factors and different signaling molecules on the development of ascomata. Ascomata development is also dependent on several developmentally regulated genes.

Sexual reproduction in ascomycetes provides insight regarding the mechanism and regulation of developmental processes. These ascomycetes are ideal model organism due to their relatively small genome size and due to the ability to culture them in the laboratory. Sexual reproduction in fungi reduces the accumulation of deleterious mutations, thus leading to better adaptability to changing environmental conditions. Despite intensive studies of the regulation and development of ascomata, relatively little is known regarding signals involved in the formation of different cell types. The different shapes of ascomata impact the dispersal of spores and only four main types have been described. However, only around one percent of the estimated number of fungi have been described so far. Therefore, future studies could potentially allow the discovery of more types of ascomata. The dikaryotic phase is an important phase in fungal sexual development, but the signaling events responsible for the maintenance of the dikaryon and the regulated entry into karyogamy remain unclear.

From Roland Thaxter to the Present: Synergy Among Mycologists, Entomologists, Parasitologists

Laboulbeniales were discovered in the middle of the 19th century, rather late in mycological history (Anonymous, 1849; Rouget, 1850; Robin, 1852, 1853; Mayr, 1853). After their discovery and eventually their recognition as fungi, occasional reports increased species numbers and broadened host ranges and geographical distributions; however, it was not until the fundamental work of Thaxter (1896, 1908, 1924, 1926, 1931), who made numerous collections but also acquired infected insects from correspondents, that the Laboulbeniales became better known among mycologists and entomologists. Thaxter set the stage for progress by describing a remarkable number of taxa: 103 genera and 1260 species.

Fewer than 25 species of *Pyxidiophora* in the Pyxidiophorales are known. Many have been collected rarely, often described from single collections and never encountered again. They probably are more common and diverse than known collections indicate, but their rapid development in hidden habitats and difficulty of cultivation make species of *Pyxidiophora* easily overlooked and, thus, underreported (Blackwell and Malloch, 1989a,b; Malloch and Blackwell, 1993; Jacobs *et al.*, 2005; Gams and Arnold, 2007). The group is crucial, however, because of its taxonomic position within the Laboulbeniomyces to provide a morphological link between the thallus-forming Herpomycetales and Laboulbeniales (Haelewaters *et al.*, 2021c) and perithecial ascomycetes (Fig. 1).

Cooperation among entomologists, botanists, and parasitologists easily goes back as far as the mid-19th century as evidenced by the correspondence of Charles Darwin and Henry Denny, an entomologist and authority on parasites (Darwin, 1865). Likewise, Thaxter's major contributions were possible not only from his own field collections and museum visits, but also from specimens sent to him by a wide network of entomologists. These contacts provided access to many hosts from places never visited by Thaxter, such as the African continent and southeastern Asia, from which he described many taxa. After Thaxter's death, most of the Laboulbeniomyces literature concerned regional studies and parasite–host lists in different geographical regions, including Belgium and the Netherlands (De Kesel and Rammeloo, 1992; De Kesel *et al.*, 2020; Haelewaters and De Kesel, 2020); Finland (Huldén, 1983); Germany (Scheloske, 1969); Poland (Majewski, 1994, 2003), the Iberian Peninsula (Santamaría, 1998, 2003), and Japan (Sugiyama, 1973). Many species reported by these authors continue to result from hosts provided by entomologists or from museum insect collections (e.g., Santamaría *et al.*, 2016; Haelewaters and Rossi, 2017; Kaishian and Weir, 2018; De Kesel and Haelewaters, 2019; Kaishian *et al.*, 2020; Rossi and Leonardi, 2020). Currently, projects focusing on Laboulbeniales associated with the bat fly parasites of bats, revive the tradition of collaboration among mycologists, entomologists, and even mammalogists (Walker *et al.*, 2018; Haelewaters *et al.*, 2021a).

The major contribution of Benjamin (1971) made the massive work of Thaxter more accessible; he also reviewed his own work and the research of the post-Thaxter half century. Fifty years later, Haelewaters *et al.* (2021c) reviewed the developments in Laboulbeniomyces of yet another half century.

The Winding Road to Molecular Phylogenetics: Progress in the Study of Laboulbeniomyces

Advancement in the study of Laboulbeniales was initially slow because of their minute size, limited morphological traits to distinguish them among themselves, inability of most taxa to grow in axenic culture, and absence of comparative traits to place them among other fungi. Microscopes provided early evidence of the existence of Laboulbeniales, previously unknown minute ectoparasites of arthropods, and led to their recognition as fungi. After their fungal character was confirmed, better communication and transportation means enabled the discovery of additional species and broadened geographical and host ranges. Transmission electron microscopy (TEM), although less successfully applied to Laboulbeniomyces compared to other groups of fungi, brought critical proof of free cell formation involving an ascospore-delimiting membrane in ascosporeogenesis, the hallmark of the Ascomycota (Hill, 1977). Even limited success at cultivation has helped to cast light on nutritional requirements of certain Laboulbeniomyces (Whisler, 1968; Blackwell and Malloch, 1989b; Jacobs *et al.*, 2005).

[☆]We dedicate this chapter to Dr. Donald H. Pfister, Curator of the Farlow Reference Library and Herbarium of Cryptogamic Botany and Asa Gray Professor of Systematic Botany at Harvard University. For almost half a century, he has been committed to preserving critical research materials and promoting their use while conducting his own extensive research and mentoring students of all ages.

Fig. 1 Evolutionary hypotheses about the relationships between clades within the class Laboulbeniomyces. **A.** Six-locus phylogeny based on 434 isolates, including 4 Laboulbeniomyces isolates (modified from Schoch *et al.*, 2009). **B.** SSU rDNA phylogeny based on 65 isolates (modified from Goldmann and Weir, 2018). **C.** Three-locus rDNA phylogeny based on 61 isolates (modified from Haelewaters *et al.*, 2019d). **D.** Two-locus rDNA phylogeny based on 75 isolates (modified from Blackwell *et al.* 2020). Nodes without support are marked with a red “x”.

Despite the discovery of free cell formation, disputes over the taxonomic position of the Laboulbeniales persisted (Cavalier-Smith, 1998; 2000), until the development of the polymerase chain reaction (PCR). Since the mid-1990s, DNA characters and ever-increasing taxon sampling have begun to unravel evolutionary relationships of Laboulbeniomyces, to gain a better picture of their diversity, and to delineate species with innumerable discrete characters compared to those provided by morphology (e.g., Blackwell, 1994; Weir and Blackwell, 2001b; Goldmann and Weir, 2012; 2018; Haelewaters *et al.*, 2018, 2019d, 2021c; Blackwell *et al.*, 2020). Based on sequences of the small subunit (SSU) of the ribosomal RNA gene (rDNA), Weir and Blackwell (2001b) rejected a Cavalier-Smith (1998, 2000) hypothesis and showed Laboulbeniales + Pyxidiophorales to be a strongly supported single clade, class Laboulbeniomyces, within the Ascomycota. However, no assessment of the relationship of the class among other ascomycetes was possible due to lack of support primarily due to absence of adequate sampling of ascomycete taxa. Schoch *et al.* (2009) presented the phylogenetic reconstruction of an Ascomycota-wide six-locus dataset and found strong support for the sister relationship of the classes Laboulbeniomyces and Sordariomycetes, suggestive of a single origin of perithecial fungi.

Based on SSU rDNA, Goldmann and Weir (2018) published the taxonomically broadest molecular phylogeny of the Laboulbeniomyces to date. Several lineages were supported within the class and the problematic filamentous conidial insect ectoparasites, *Chantransiopsis* and *Tetrameromycha*, were included in the class. In addition, a sequence of *Herpomyces* from Haelewaters *et al.* (2015b) fell outside of the Laboulbeniales in an unresolved position based on Bayesian inference or in an unsupported clade with *Laboulbeniopsis* using maximum likelihood criteria. Goldmann and Weir (2018) considered this analysis to be supportive of the placement of *Herpomyces* in the suborder Herpomycetinae (*vide* Tavares, 1985). A three-locus phylogenetic reconstruction led Haelewaters *et al.* (2019d) to elevate Herpomycetinae to order level. This move resulted in recognition of three major lineages in the class Laboulbeniomyces: Herpomycetales, Laboulbeniales, and Pyxidiophorales.

Members of Laboulbeniales and Herpomycetales, arthropod biotrophic ectoparasites, are characterized by the formation of a non-hyphal, three-dimensional thallus of up to a few thousand cells. In contrast, species of arthropod-dispersed Pyxidiophorales are dependent on other fungi for enhanced growth or as hosts for mycoparasites; they develop hyphae and produce perithecia. It is interesting to note that because Herpomycetales and Laboulbeniales do not form a monophyletic lineage, the thallus may have originated independently in these two orders (Fig. 1; Blackwell *et al.*, 2020; Haelewaters *et al.*, 2021c). There are, however, some species of *Pyxidiophora* known to produce 3-dimensional cell divisions resulting in limited parenchymatous areas in parts of the mycelium and in older ascospore-derived conidial states attached to mites in moist chambers (Blackwell and Malloch, 1989b). The three formally described orders and two informal clades supported by DNA analysis are discussed below.

Thallus-Forming Ectoparasites

Laboulbeniales

The order Laboulbeniales with about 2325 described species in 145 genera (Kirk, 2019; Haelewaters *et al.*, 2020a) forms the most diverse fungal lineage associated with Arthropoda, predominantly insects (subphylum Hexapoda). These fungi occur selectively on the following insects: ants (order Hymenoptera: family Formicidae), beetles (order Coleoptera), cockroaches and termites (order Blattodea), crickets and allies (order Orthoptera), earwigs (order Dermaptera), flies (order Diptera), lice (order Psocodea), thrips (order Thysanoptera), and true bugs (order Hemiptera). Numerous other arthropods are also known to host Laboulbeniales, including millipedes (subphylum Myriapoda: class Diplopoda), harvestmen (subphylum Chelicerata: order Opiliones), and mites (subphylum Chelicerata: subclass Acari) (Weir and Hammond, 1997; Santamaría *et al.*, 2017; Haelewaters *et al.*, 2019d). Although beetles are parasitized by approximately 80% of described species (Weir and Hammond, 1997), they host a relatively small number of genera of Laboulbeniales (Haelewaters *et al.*, 2019b). Fewer species have been described from other groups, such as the Hemiptera (true bugs), with only 96 described species occurring across the suborder Heteroptera (Benjamin, 1967; Santamaría, 2008; Lee and Na, 2009; Kaishian and Weir, 2018; Kaishian *et al.*, 2020).

First sightings

The study of Laboulbeniales started with observations of *thalli* (multicellular units with determinate cell number) of *Laboulbenia* on carabid beetles in the 1840s and early 1850s (Anonymous, 1849; Rouget, 1850; Mayr, 1853). Some authors thought that the structures they observed were insect parts (Mayr, 1853) whereas others recognized them as living organisms. In those days, researchers referred to Laboulbeniales as “parasitic plants” (Anonymous, 1849) or even acanthocephalan worms (Kolenati, 1857). Robin (1852) was the first to recognize them as fungi, and de Bary (1884) listed the family Laboulbeniaceae as ascomycetes with doubt. The first to use the name “Laboulbeniaceae” was Peyritsch (1873). Five genera were recognized at that time – *Chitonomyces*, *Heimatomyces*, *Helmintophana* [= *Arthrorhynchus*], *Laboulbenia*, and *Stigmatomyces* – and twelve species had been described, eight of which were in the genus *Laboulbenia* (Benjamin, 1971). By the time Thaxter published his first *Contribution towards a monograph of the Laboulbeniaceae* (Thaxter, 1896), there were 28 genera and 152 species, most of which had been published in a series of preliminary papers (Thaxter, 1891, 1892, 1893, 1894, 1895).

Current versus estimated species diversity

While only 2325 species have been described thus far, many more species are expected to be discovered in years to come. A formal estimation of the species richness of Laboulbeniales was based on the results of a beetle survey in Sulawesi, Indonesia, in which 80,000 beetles were screened for the presence of Laboulbeniales to yield an overall prevalence of 0.6% (Weir and Hammond, 1997). The principal study area was a 500-ha patch of lowland rainforest. Of a total of 4026 beetle species, 127 were hosts of Laboulbeniales fungi (3.15%). Based on their data and comparisons with other studies (Huldén, 1983; Lee, 1986; Santamaría *et al.*, 1991; Majewski, 1994; Weir, 1996), the authors asserted that greater Laboulbeniales diversity is associated with moist tropical areas and beetle hosts. Provided that the number of beetle species is estimated to be 2 million and that the prevalence of Laboulbeniales on beetles is about 3%, Weir and Hammond (1997) inferred that the number of Laboulbeniales species on beetles would be 60,000. If the ratio of host species to parasite species is 2:1 (meaning that some species of Laboulbeniales are associated with multiple host species), this results in an estimated 30,000 Laboulbeniales species on beetles. Given that at least 75% of infections occur on beetles, one could assume that the total estimate of species in the order is 40,000 [15,000 – 75,000].

There have been few other detailed studies of Laboulbeniales at a given site. Huldén (1983) surveyed the Laboulbeniales of Finland and adjacent regions of what was formerly the U.S.S.R. based on the study of museum collections. About 160,000 insects representing 1100 species were screened for the presence of Laboulbeniales. A total of 166 insect species (beetles and flies) were found to be host to 88 species of Laboulbeniales, 24 of which were newly described. The overall prevalence for this study was approximately 1%, which is thought to be low. For example, in Central Europe, the rate of infection ranges from 10% to 35% (Huldén, 1983). This striking difference may be attributed to changing climatic conditions leading to higher winter mortality of potential hosts, in addition to smaller, more isolated host populations that overlap less frequently. Wide-scale studies of neotropical Laboulbeniales diversity are lacking compared to studies from temperate regions, and no comprehensive site-based study of the group has been published from the Neotropics, although one long-term inventory project has been initiated in Cusuco National Park, Honduras (Haelewaters *et al.*, 2021b). Such studies will result in a substantial addition of new biodiversity data.

The advent of molecular studies has revolutionized our understanding of organismal relationships. These techniques are of particular value when investigating cryptic species and could help sharpen estimates of species numbers within the group. However, the isolation of DNA from thalli of Laboulbeniales was an early problem to overcome, due to their inability to grow in artificial culture, minute size, and melanized tissue (Weir and Blackwell, 2001a; Haelewaters *et al.*, 2015b; Sundberg *et al.*, 2018a). It does not come as a surprise that only 12 of 174 species of Laboulbeniomyces described between 2010 and 2020 were accompanied by sequences (Fig. 2), mostly of nuclear rDNA regions, but also mitochondrial small subunit rDNA and translation elongation factor 1 α gene. As integrative taxonomy practices become commonplace in species delimitation of many groups of fungi, Laboulbeniales researchers have struggled to keep pace. However, molecular phylogenetic data have successfully clarified relationships at lower taxonomic ranks (e.g., Weir and Hughes, 2002; Goldmann and Weir, 2012; Goldmann *et al.*, 2013; Sundberg *et al.*, 2018b; Haelewaters *et al.*, 2019a; Liu *et al.*, 2020) and revealed the existence of cryptic diversity in the

Fig. 2 Number of described Laboulbeniomyces species – including *formae* – since 2010, based on morphology alone (without sequence data) versus using an integrative taxonomy approach (with sequence data).

Laboulbeniales, with *Arthrorhynchus eucampsipodae*, *Hesperomyces virescens*, and *Laboulbenia flagellata* having been recognized as species complexes (Haelewaters *et al.*, 2018, 2019b, 2020a; De Weggheleire, 2019). These findings make the 40,000-figure from Weir and Hammond (1997) a conservative estimate for species richness in the order.

Still, generating sequences for Laboulbeniales remains a challenge, especially for material from dried museum collections or specimens collected > 10 years ago. This dilemma necessitates consideration of the value of alpha-taxonomy. While researchers of certain groups, such as the fleshy mushrooms, may challenge the validity of species descriptions made in the absence of molecular characters, morphological descriptions have been critical in building foundational knowledge of Laboulbeniales. And while integrated taxonomy – the use of combined morphological, ecological, geographical, and molecular data – is an ideal to which researchers strive, Hibbett *et al.* (2016) pointed out that many researchers lack access to sufficient funding or equipment to generate molecular data. These researchers are often based in tropical areas where most of the world's undescribed species reside. Because millions of fungal taxa remain undiscovered, it seems prudent for taxonomists to continue working using available resources with the understanding that future molecular phylogenetic work may confirm or shift species limits. Concurrently, collaboration between fungal molecular systematists and classically trained taxonomists should be the end goal.

Museum collections, citizen science projects, and social media

There is a large discrepancy between the number of described species of fungi (138,000, Kirk, 2019) and the number of estimated species (2.2–6 million, e.g., Hawksworth and Lücking, 2017). A common inquiry asks, *where are the millions of missing fungi?* Wijayawardene *et al.* (2020) put forward five sources of undescribed fungi: (1) habitats that are naturally diverse but poorly studied, (2) cryptic taxa, (3) fungal collections that might contain cryptic or new species hidden under current names, (4) molecular novelties, and (5) natural history collections including plant herbaria and entomological collections. Indeed, insect collections are a treasure trove for Laboulbeniales researchers. Thalli of Laboulbeniales persist indefinitely on the host body whether the host is preserved in ethanol or dried and pinned. Because museum collections often contain a wide array of taxa from a broad range of localities, researchers utilizing collections can pursue a research scope focusing on specific geographical areas and/or taxa. Making use of museum collections for research as opposed to conducting fieldwork has logistical advantages, saving time and expenses, and circumventing the need to kill hundreds to thousands of insect specimens to find only a few ones hosting Laboulbeniales. Another huge advantage is that the host is often already identified by an expert.

Collections have been used to investigate an array of questions about biodiversity, taxonomy, biogeography, and host usage patterns of Laboulbeniales. Blackwell (1980a,b) screened 2517 nycteribiid bat flies at the Natural History Museum (London) and found thalli of *Arthrorhynchus* on 56 specimens. She used this material along with Thaxter's slide mounts from the Farlow Herbarium to study fungal development and morphology, host associations, and within-species phenotypic plasticity. Haelewaters *et al.* (2015c, 2019b) reported nine new country records of Laboulbeniales (Canada, USA, Croatia, Slovenia, Ukraine, DR Congo) based on dried collections of Carabidae, Coccinellidae, and Staphylinidae from the Harvard Museum of Comparative Zoology, the American Museum of Natural History (New York), Tupper Center of the Smithsonian Tropical Research Institute (Ancon, Panama), and the Collection d'insectes du Québec (Canada). Kaishian and Weir (2018) and Kaishian *et al.* (2020) described eight new species of the genera *Laboulbenia* and *Prolixandromyces* based on material from the collection of Dr. John T. Polhemus, Department of Entomology, Smithsonian National Museum of Natural History (Washington, D.C.). Santamaría *et al.* (2016)

utilized the millipede collection preserved at the Natural History Museum of Denmark (Copenhagen) to describe nine new species of *Rickia*. Haelewaters *et al.* (2017) proposed that a lag time occurred between establishment of the invasive alien ladybird *Harmonia axyridis* in nature and acquisition of *Hesperomyces virescens* by this host. The authors based their findings on the study of 7404 ladybirds collected in 1991–2015, of which 521 were from eleven museum collections in North America and Asia.

Contributions from citizen scientists have been of great importance to biodiversity research since the 19th century. Citizen science projects have gained more traction in recent years and examples of large-scale projects dependent on input from non-professionals, are commonplace (e.g., Douglas, 2016). Haelewaters *et al.* (2019c) downloaded and curated North American occurrences of *Hesperomyces virescens* associated with the invasive alien species *Harmonia axyridis* from citizen science platforms Bugguide and iNaturalist. All records were used to build a map at Beetlehangers.org (see “Relevant Websites section”), the primary aim of which is to track the distributional range of the ladybird–parasite association through time. As another example, Báthori *et al.* (2017) reported a new country record of *Rickia wasmannii* from Greece, which was found and identified using the digital image collection at AntWeb (see “Relevant Websites section”). Finally, Santamaría *et al.* (2020b) described a new species of *Trogloomyces*, initially discovered in a photograph of a millipede shared on Twitter (see “Relevant Websites section”) and then found on millipedes at the Natural History Museum of Denmark and the Muséum National d’Histoire Naturelle in Paris. These recent studies also speak to the timelessness of natural history collections and their continued value in modern research.

Classification of the order

Roland Thaxter not only contributed invaluable taxonomic additions, he was also the first – and for a long time the only one – to propose a classification system for the order. At the time of the first volume of his *Contribution towards a monograph of the Laboulbeniaceae* (Thaxter, 1896), what we currently refer to as the Laboulbeniales was designated a family, Laboulbeniaceae. Thaxter (1896) split up the Laboulbeniaceae into two “groups”, the Exogenae and Endogenae. Development of spermatia, gametes produced on the appendages, was the sole criterion for grouping of taxa. The Exogenae included genera with species that form spermatia exogenously. They are borne on intercalary cells or terminally on short branchlets. Only the genera *Ceratomyces* and *Zodiomyces* were part of this Exogenae group. The Endogenae comprised taxa in which spermatia are formed within antheridia. This group included two “orders”: Laboulbeniae (with simple antheridia, 15 genera) and Peyritschieae (with compound antheridia, 11 genera).

Thaxter (1908) accepted the ordinal name Laboulbeniales, which included the recently described genus *Herpomyces* (Thaxter, 1902), and replaced the terms Exogenae and Endogenae by subordinal names Laboulbeniinae and Ceratomycetinae. The two subdivisions of the original “group” Endogenae were replaced by families Laboulbeniaceae and Peyritschieaceae. Thaxter did not recognize a family within the Ceratomycetinae. The name Ceratomycetaceae, now widely accepted, was introduced by Maire (1916) as a *nomen nudum*, later validly published by Colla (1934). This scheme of organizing taxa was widely accepted until Tavares (1967, 1985) introduced new characters for classification of the Laboulbeniales: perithecial development and perithecial wall structure. Later, Goldmann and Weir (2018) found that the number of perithecial wall cells is phylogenetically informative across the order Laboulbeniales; the authors described a progressive reduction of number of perithecial wall cells in the four vertical rows. Thaxter’s (1908) two suborders, two families and twenty tribes were reorganized to two suborders, four families, six subfamilies, 13 tribes and 28 subtribes in Tavares’ (1985) classification system.

Tavares (1985) recognized three families in the suborder Laboulbeniinae: Ceratomycetaceae, Euceratomycetaceae, and Laboulbeniaceae (Majewski, 1994; Santamaría, 2003). Ceratomycetaceae comprises twelve genera: *Autoicomyces*, *Ceratomyces*, *Drepanomyces*, *Eusynaptomyces*, *Helodiomyces*, *Phurmonomyces*, *Plectomyces*, *Rhynchophoromyces*, *Synaptomyces*, *Tettigomyces*, *Thaumasiomyces*, and *Thripomyces*. Synapomorphic characters are (1) the primary receptacle consisting of a single series of superposed cells and (2) cells VI and VII being successive, intercalary cells of the primary receptacle (Tavares, 1985). In the Euceratomycetaceae, cells VI and VII are successive cells of the lateral secondary appendage arising from the primary appendage. The lateral appendage extends beyond the base of the perithecium (arising from cell VII). Depending on the genus, there may be a single perithecium or multiple ones. Genera included in the Euceratomycetaceae are *Cochliomyces*, *Colonomyces*, *Euceratomyces*, *Euzodiomyces*, and *Pseudoecteinomyces*.

Taxa in the genus *Euzodiomyces* are exceptional among Laboulbeniales in the construction of their primary receptacle, which is many-celled and parenchymatous (Tavares, 1985; Santamaría, 2003). Other than in *Euzodiomyces*, this feature is only present in the genera *Columnomyces*, *Kainomyces*, *Scepastocarpus*, and *Zodiomyces*, all of which are classified in the Laboulbeniaceae (Rossi *et al.*, 2016). All genera but one (*Tettigomyces*) in Ceratomycetaceae are associated with aquatic hosts, whereas those in Euceratomycetaceae have terrestrial hosts. Finally, the family Laboulbeniaceae is recognized by the tiers of perithecial outer wall cells, which are four or five in number and unequal in height. Although the genus *Zodiomyces* has perithecial outer wall cells that are arranged in eight tiers subequal in height, Tavares (1985) also placed this genus in Laboulbeniaceae, in its own subfamily Zodiomycetoidae. This is in stark contrast to Thaxter (1908) who had placed *Zodiomyces* in the suborder Ceratomycetinae.

Currently, the classification system of Tavares (1985) is still in use, although molecular phylogenetic studies have repeatedly shown that several taxa within this system are polyphyletic. At least three subtribes, two tribes, and two subfamilies are polyphyletic (Goldmann and Weir, 2018; Haelewaters, 2018). In addition, *Herpomyces* was recently removed from the Laboulbeniales and placed in its own order with strong support from multiple sources (Haelewaters *et al.*, 2019d; Blackwell *et al.*, 2020). In the SSU rDNA phylogeny of Haelewaters (2018), four genera with species that are associated with aquatic hosts were placed basally in the Laboulbeniales order. This might be seen as evidence for an ecological viewpoint rather than, or in addition to, a structural-based one. All in all, while the classification of the Laboulbeniales order is in urgent need of complete revision, current taxon and character sampling is far too insufficient to make changes that are taxonomically stable. Continued development of molecular

protocols – optimized for scarce material, e.g., including a whole-genome amplification step prior to PCR – will lead to the progress needed to propose a stable evolutionary hypothesis for the order.

Notes on ecology

Where Laboulbeniales receive their nutrients from is not entirely understood, which can be partly explained by the presence of taxa without a penetrating haustorium (Tragust *et al.*, 2016). In addition, to date, attempts to obtain axenic cultures of Laboulbeniales have failed whereas transmission experiments of Laboulbeniales among hosts have been used to prove specificity and host-related nutritional requirements. Several authors put forward different hypotheses about nutrient uptake—including chitin of the integument, secretions from exocrine glands, substances available at the cuticle (waxy substances, components from plants, substrate, microbiota, host fecal materials), and waxy lipids produced by the epidermal cells. It is most widely accepted that nutrition is obtained through the attachment area. Support for this hypothesis came from Scheloske (1969) who injected Nile sulfate dye into an insect and observed it flowing from elytral tissues to *Laboulbenia* thalli.

Since Laboulbeniales are phenotypically plastic, their morphology can vary dramatically depending on the position on the host's integument as well as the sex of the host. Some authors considered these morphologies as separate taxa (Thaxter, 1926; Benjamin and Shanor, 1952; Benjamin, 1967), whereas others described them as morphotypes of the same biological species (Rossi and Kotrba, 2004; Rossi, 2006; Rossi and Proaño Castro, 2009; Santamaría and Faille, 2009; Haelewaters and Rossi, 2017). Based on molecular analysis, the phenomenon of position specificity was recently confirmed for Laboulbeniales from aquatic hosts (Goldmann and Weir, 2012); speciation was not connected to nutrition of the fungus, but to a highly specific and precise transmission of spores during copulation. However, the understanding of how Laboulbeniales from terrestrial hosts are directly transmitted, mainly by copulation (Scheloske, 1969), made an end to position specificity and sex-of-host specificity.

The need for a living host is clear, but the occasionally reported dramatic host shifts have remained unexplained for a very long time. Examples are *Rickia wasmannii* in ant nests parasitizing both *Myrmica* ants (main host) and co-habiting arthropods, which belonged to a different order (Diptera) and even subphylum (Chelicerata) (Pfliegler *et al.*, 2016), and *Stichomyces conosomatis* in a subterranean cave on *Speonemadus algarvensis* (Leiiodidae), which represented the only report of this fungus on a host other than species of *Sepedophilus* (Staphylinidae) (Reboleira *et al.* 2017). Scheloske (1969) and later Majewski (1994) and De Kesel (1997) showed that a single species of *Laboulbenia* can have main, occasional, and accidental hosts. In most cases, these hosts occupy the same habitat. Based on his observations, Scheloske (1969) stated that plurivorous Laboulbeniales need both the host and its habitat and launched the concept of “ecological specificity” – although the term “habitat specificity” is more accurate because host specificity also assumes resource availability and niche specialization.

De Kesel (1996) carried out experiments testing the impact of habitat on growth, development, and transmission. Via a gradient analysis it was found that under certain habitat conditions, *L. slackensis* can be transmitted and will develop successfully on a series of atypical hosts. The potential host range of Laboulbeniales is much wider than initially thought and opportunities for host shifting are therefore entirely governed by the host, its behavior (habitat choice), and life history. Although host shifting of Laboulbeniales is possible under certain conditions, there are some barriers. Species of Laboulbeniales are fairly isolated on their respective host populations. This is because direct transmission of ascospores is mostly intraspecific (among hosts of the same species), in the form of grooming, copulation, and random aggregation contacts (*Herpomyces*: Richards and Smith, 1955; *Hesperomyces*: Nalepa and Weir, 2007; *Laboulbenia*: De Kesel, 1995a,b; *Rickia*: Haelewaters *et al.*, 2015a). Indirect transmission is negligible because of the short lifespan of ascospores (De Kesel, 1995b; Cottrell and Riddick, 2012), and opportunities for interspecific contacts with other hosts are often few because of their separation in time and space—unless they cohabit the same microhabitats.

Most species of Laboulbeniales only develop on adults; transmission can only take place if adult generations overlap. Because of this, suitable hosts that are parasitized by a given species of Laboulbeniales in warmer areas lack the parasite in colder localities (northern, alpine), where they overwinter as larvae (Huldén, 1983). Parasite prevalence, that is, the number of parasitized host specimens in a population, fluctuates greatly throughout the year and is affected by the host life cycle (spring breeders vs. autumn breeders), the emergence period of new generations (Scheloske, 1969), and host population density (De Kesel, 1995a). Thallus density, the number of thalli on a host individual, on the other hand, seems to increase with increasing age of the host (Haelewaters *et al.*, 2015a; De Kesel *et al.*, 2016). This is an important feature because it boosts opportunities for transmission of ascospores between old and new generations.

Thallus morphology

The thallus (Fig. 3) is a multicellular unit with a restricted number of cells, derived from two-celled ascospores through a defined number of mitotic divisions in multiple planes (Blackwell *et al.*, 2020). A primary septum separates the larger cell of the ascospore from the smaller one. This septum is often visible by its thickness and color, even in mature thalli. The main axis of the thallus is formed by the receptacle, which is the part of the multicellular unit that is connected to the host by means of a foot. The receptacle and foot are derived from the larger cell of the ascospore, which is released first from the perithecium. Additional divisions of particular cells of the receptacle produce the perithecium or perithecia. The perithecium is the only spore-forming structure of the Laboulbeniales; there are no asexual spores. The smaller cell of the ascospore produces the primary appendage system, which carries the spermatia-producing antheridia. The entire ontogeny, from ascospore to mature thallus, was studied for a few *Laboulbenia* species (Tavares, 1985; De Kesel, 1989). In terms of orientation, the anterior side is the one on which the perithecium

Fig. 3 Herpomycetales and Laboulbeniales. **A–B.** *Herpomycetes chaetophilus* on *Periplaneta americana*. **A.** Thalli attached to the setae of an antenna. **B.** Single thallus of *H. chaetophilus* attached to an antennal seta. Pencil drawing by Jingyu Liu. **C.** A *Harmonia axyridis* ladybird with tufts of *Hesperomyces* thalli on its mouthparts and left eye. **D.** Growth positions of *Chitonomyces* thalli on the left elytral margin of *Laccophilus hyalinus*; thalli of *C. melanurus* (arrowhead) are found above and on the epipleuron, whereas *C. paradoxus* thalli (arrow) consistently grow on the lower part of the margin. **E–H.** Spermatia-producing structures. Pencil drawings by Jingyu Liu. **E.** Appendage cells forming spermatia exogenously (arrowhead) in *Drepanomyces* sp. (Ceratomycetaceae). **F.** Simple antheridia (arrowhead) in *Arthrorhynchus nycteribiae* (Laboulbeniaceae). **G.** Tufts of simple antheridia (arrowhead) in *Laboulbenia disenochi* (Laboulbeniaceae). **H.** Compound antheridium, with spermatia leaving the chamber through a single opening (arrowhead), in *Neohaplomyces medonalis* (Peyritsiaceae). **I.** Mature thallus of *Laboulbenia fuscata* from *Pterostichus* sp. collected in Argentina; the receptacle is formed by cells I through V (labeled); cells III, IV, and V in *Laboulbenia* are often referred to as the androstichum. From the Roland Thaxter collection of slide mounts at the Farlow Herbarium. **J.** Mature thallus of *Hesperomyces virescens* (sensu lato) from *Harmonia octomaculata* collected in Micronesia; annotated are cells I, II, and III of the receptacle, the appendage (A) with simple antheridia, and the perithecium (P) with four tiers of wall cells (w_1 to w_4). Scale bars A 500 μm ; B, D 50 μm ; I, J 100 μm .

is located, whereas the posterior side is the side away from the perithecium. Other authors use ventral and dorsal for anterior and posterior, respectively.

Receptacle

The primary receptacle forms the base for all parts of the thallus. Its shape and structure are extremely variable within the order, and this variability is an important criterion in generic delimitation. Apparently, the lower cell of the ascospore generally divides into 3 cells denoted by Roman numerals I, II, and III. Further divisions in different planes may take place, depending on the genus. Many genera, those in the subtribe Stigmatomycetinae, have only those three cells in the receptacle but their positions are variable with respect to one another. Cell I is the basal cell, forming the connection with the host's integument (referred to as the foot). Multiple divisions of cell I can occur, for example in female thalli of *Dimeromyces*. These secondary cells will further give rise to

perithecia or sterile appendages. Cell II, the suprabasal cell, generates the perithecium by successive divisions. Cell II undergoes multiple divisions in many genera, forming an elongate uniseriate receptacle. Examples of genera with this structure are *Chaetomyces*, *Ecteinomyces*, *Filariomyces*, and *Ormomyces*. Secondary divisions of cell III can occur. For example, in the genus *Laboulbenia*, these divisions form cells IV and V. The entire complex of cells III to V is called androstichum (Fig. 3f). Some species of *Laboulbenia* have an undivided cell III + IV or cell III + IV + V (e.g., *L. nisotrae*, *L. obesa*, *L. richardiana*).

Perithecium

The perithecium is derived from the receptacle, in species without secondarily divided receptacle cells it arises from divisions of cell II. Benjamin (1971) described three types of perithecial development. In the first type, a single cell arises laterally from the receptacle to divide into a lower and upper cell. The lower cell, by continued divisions, gives rise to the perithecial stalk cell (VI), secondary stalk cell (VII), and basal cells m, n, and n'. The upper cell will give rise to the female sexual organ, which initially comprises three cells: basal carpogenic cell, trichophoric cell, and terminal trichogyne. The trichogyne is a thin appendage-like outgrowth of the young perithecium. It may or may not develop into a multicellular simple or branched structure, depending on the species. Its function is to receive spermatia. Before the perithecium is mature, the trichogyne will deteriorate, often leaving a visible scar. This "carpogonial upgrowth" is enveloped by the perithecial walls, which arise from cells m (forming a single vertical row of wall cells) and n and n' (forming three rows).

After interception by the trichogyne, the male nucleus from a spermatium will migrate to the carpogenic cell, thus resulting in the formation of an ascogenous cell (or multiple ones by mitotic divisions), in which both the male and female nuclei are present. This is the dikaryotic phase of the Laboulbeniales life cycle. Asci are produced by mitotic divisions of the ascogenous cells in multiple planes. Upon fusion of the two nuclei, the diploid ascus mother cell is formed, which after meiosis gives rise to an ascus with 4 ascospores. This developmental type was described and illustrated by Thaxter (1896) for *Laboulbenia elongata*, *Peyritsiella geminata*, and *Stigmatomyces baeri*. According to Benjamin (1971) there is only one genus of Laboulbeniales that does not follow this type of development; *Coreomyces* forms what Thaxter (1908) named a pseudoperithecium.

The mature perithecium is more or less elongated and narrowed towards the tip (distally). Sometimes there is a clear differentiation into a rounded or ovoidal venter and a narrow neck, terminating in an ostiole. The perithecial wall cells surrounding the ostiole often form distinct lips (e.g., in *Hesperomyces*) or (sub)apical outgrowths (e.g., in *Diphymyces*). The perithecium usually consists of a well-defined number of cells. The perithecial wall cells appear in two layers; the external wall cells are clearly visible and have taxonomic importance (Tavares, 1985; Majewski, 1994). The most ancestral perithecium is the one in which each of the four vertical rows of outer wall cells consists of many cells that are equal in height, as in Ceratomycetaceae. This was stated by Tavares (1985) and supported by the use of sequence data (Goldmann and Weir, 2018; Haelewaters, 2018). Morphological studies of the genera *Nycteromyces* and *Polyandromyces* (Dimorphomycetaceae) failed to distinguish perithecial cell walls (Thaxter, 1920, 1924; Haelewaters, 2018). Presumably this represents a highly derived situation (Tavares, 1985).

Appendage and antheridia

The primary appendage usually is a direct continuation of the receptacle axis. It is produced by divisions of the upper, smaller cell of the ascospore. In some genera, the primary appendage is very simple, consisting of one or two cells only. Examples are *Dioicomyces* and *Filariomyces*. In very few species the appendage can even become aborted (Tavares, 1985). Well-developed primary appendage systems exist in many species of, e.g., *Corethromyces* and *Laboulbenia*. Sometimes, the original spore apex remains visible at maturity as a spinose process because the branches are formed at a level below the apex. This process is an important feature to identify species in the genera *Acompsomyces*, *Eucantharomyces*, *Ilyomyces*, and *Rhachomyces* (Santamaría, 2003, 2006; Haelewaters, 2013; Santamaría et al., 2020a). The primary appendage system of *Laboulbenia* deserves extra attention. Its basal cell, called insertion cell or cell e, is flattened and usually obscure and carries the inner and outer appendages. The inner appendage bears flask-shaped, simple antheridia. The outer appendage is usually longer, simple or branched, and almost always sterile.

The primary appendages of *Chitonomyces* and *Hydraeomyces* break off early, right above the constricted black septum (Tavares, 1985). The primary appendages of *Columnomyces* and *Diphymyces* are usually partly or completely broken off (Thaxter, 1918, 1931; Benjamin, 1955; Haelewaters et al., 2014; De Kesel and Haelewaters, 2019; Perreau et al., 2021). This damage has been linked to the behavior of the host insects, Cholevinae (Coleoptera, Leiodidae). Cholevine beetles have evolved a largely underground lifestyle and make extensive use of narrow channels and tunnels in the soil, which may account for breakage of parts of Laboulbeniales thalli on these hosts (Sokolowski, 1942). Also the extensive appendage system of *Laboulbenia clivinalis* regularly breaks off (and regenerates, Majewski, 1994). Similar to cholevines, *Clivina fossor*, the host of *L. clivinalis*, has a partly subterranean lifestyle (De Kesel, 1995a).

When sterile or antheridial branches are derived from the lower cell of the ascospore, they are referred to as secondary appendages. All appendages of *Scepastocarpus* and *Zodiomyces* are secondary in origin. Little is known about the function of sterile appendages, whether primary or secondary. Cava (1899) speculated that thalli could retrieve nutrients from the environment by means of their sterile appendages. De Kesel (1996) showed experimentally that the successful establishment of *Laboulbenia slackensis* requires not only a suitable host but also favorable environmental conditions, which could be linked to the extensive appendage system of that species. Recently, Tragust et al. (2016) found no visible penetration damage at the host integument using light and electron microscopy techniques in four species of Laboulbeniales, revealing the necessity for alternative explanations to the hypothesis that Laboulbeniales may only receive nutrients through a haustorium. Further experimental work might be directed

toward the function of the sterile appendages; this would entail injecting dye in thalli of both haustorial and non-haustorial representatives of Laboulbeniales (see *Notes on ecology*).

Spermatia are produced either exogenously or endogenously within simple or compound antheridia (Fig. 3E–H). Exogenous spermatial formation has mainly been observed in species that have aquatic hosts (Weir and Blackwell, 2005), such as species of *Ceratomyces* and *Zodiomyces*. In these genera, spermatia may be borne on intercalary cells or terminally on a short branchlet (Majewski, 1994). Simple antheridia are flask-shaped, with the neck serving as a discharge tube. Sometimes, old antheridia can proliferate into sterile branches, this is often seen in members of *Laboulbenia*. In some genera, corner cells or intercalary cells of the appendage serve as antheridia with only the discharge tube being free. Most Laboulbeniales possess simple antheridia. Compound antheridia only occur in taxa of Monoicomycetoideae and Peyritschelloideae. Antheridial cells are structurally united and release their spermatia into a chamber that has a single opening. In the subfamily Monoicomycetoideae, compound antheridia are distally rounded and lack a discharge tube. Compound antheridia with an elongated neck occur in the Peyritschelloideae. This observation led Faull (1911) to suggest that compound antheridia had arisen independently more than once. Almost a century later, this suggestion was confirmed based on molecular phylogenetic data (Goldmann and Weir, 2018; Haelewaters, 2018). Antheridial characters were important to Thaxter's (1896, 1908) – obsolete – classification system.

Ascospores

The ascospores of Laboulbeniales are two-celled, hyaline, elongate, and spindle-shaped. They are typically surrounded by a mucilaginous envelope, which provides adhesiveness. In addition, the foot is usually melanized before release. The ascospores are almost exclusively transferred by the activities of the host (De Kesel, 1995a; Cottrell and Riddick, 2012). Ascospores are produced in perithecia such that their larger cell, which becomes attached to the host, is directed upwards and subsequently released first.

Herpomycetales

Until very recently, discussions of “Laboulbeniales” included the order Herpomycetales, which is now separated based on molecular and morphological evidence. Herpomycetales was erected following the molecular phylogenetic analysis of a three-locus rDNA dataset. The order is monotypic, with the dioecious *Herpomyces* as the single genus. The genus currently includes 27 species, all described between 1902 and 1931 except for two recent species, *H. shelfordellae* and *H. spegazzinii* (Haelewaters et al., 2019d; Gutierrez et al., 2020). All species are exclusively associated with cockroaches (Blattodea), both nymphs and adults. Thalli of *Herpomyces* are developmentally and morphologically distinct (Tavares, 1965, 1966, 1980, 1985; Hill, 1977). This evidence provides additional support for the idea that thallus formation in the two orders Herpomycetales and Laboulbeniales has evolved independently (Fig. 1D). For example, whereas both orders have double-layered perithecia, the way their perithecial walls are formed is fundamentally different. Ascus formation, number of ascospores per ascus, and positioning of the ascospore septum are also different between Herpomycetales and Laboulbeniales (reviewed in Haelewaters et al., 2019d). *Herpomyces* also perforates its host in multiple places whereas Laboulbeniales perforate their host only at the single point of attachment or not at all (Tragust et al., 2016). Species of *Herpomyces* can vary in their morphology depending on their position on the host (Thaxter, 1908; Tavares, 1985), as is also the case with some members of Laboulbeniales.

The thallus of *Herpomyces* has a differently structured receptacle compared to genera of Laboulbeniales. The primary receptacle of female thalli is small, typically consisting of four cells. The suprabasal cell gives rise to a secondary axis that consists of a series of narrow cells each perforating the integument of the host by small haustoria. Male thalli are similar in that they have a primary axis, usually consisting of four superposed cells, and that the suprabasal cell may produce a secondary axis; both the third and fourth cell may give rise to a single cell or branch carrying antheridia. The perithecium of Herpomycetales has four vertical rows of outer wall cells each consisting of many cells equal in height. This condition, which is also seen in Ceratomycetaceae, has been considered the “ancestral” perithecium but the situation is likely more complex provided the thallus of Herpomycetales and Laboulbeniales may have evolved independently. This evolutionary hypothesis is supported by the development of the perithecium that is different in *Herpomyces* and Laboulbeniales. The entire perithecium of *Herpomyces* develops from an outgrowth of the suprabasal cell of the 4-celled primary receptacle, by subsequent transverse and longitudinal divisions (Tavares, 1965, 1966). The carpogonial upgrowth(s) is initiated by a specific outer wall cell. Finally, in the *Herpomyces* ascus mother cell, mitosis will take place after meiosis, forming an ascus with 8 ascospores, as do most of the other species in Ascomycota. The entire ontogeny, from ascospore to mature thallus, was studied for *Herpomyces ectobiae* (Tavares, 1985).

Contrary to infections with most species of Laboulbeniales, *Herpomyces* infections often display a high parasite prevalence. For example, Richards and Smith (1955) mentioned a 100% prevalence of *H. stylopygae* on 50 *Blatta orientalis* cockroaches. Similarly, Wang et al. (2016) reported a 96.8% prevalence of *H. chaetophilus* on 31 *P. americana* roaches. This can be explained by the fact that populations of cockroaches are often densely packed, they occur in moist, damp environments, and they are in constant contact with each other, for example by their grooming behavior. Pfliegler et al. (2018) studied eleven populations of cockroaches, originating from either pet stores, biological supply companies, or laboratory colonies. In eight populations, infections with *Herpomyces* spp. were detected, and parasite prevalence ranged between 8.77% and 86.36%. The authors suggested that at least some species of *Herpomyces* are spread by globally invasive host species as well as through the international pet and pet food trade.

Pyxidiophorales, Hyphal Mycoparasites

The order Pyxidiophorales contains the perithecial genus *Pyxidiophora* and *Mycorhynchidium*, reported to vary by its cleistothecial form. *Pyxidiophora* and close relatives are contact mycoparasites varying in their reliance on a host fungus from greatly improved growth to obligate fungal biotrophy (Kirschner, 2003; Jacobs *et al.*, 2005). The life cycle of most species of *Pyxidiophora* is complicated, consisting of three different morphs: (1) a dispersal morph (*Thaxteriola* state) derived from an ascospore that delivers conidia to a fresh substrate, (2) a conidial morph developed on hyphae, and (3) an ascospore-producing perithecial morph to come full circle (Fig. 5). Only 21 species of *Pyxidiophora* have been formally described although it is unclear whether they are all distinct (Lundqvist, 1980; Doveri and Coué, 2006). At least five undescribed species are known (M. Blackwell and M. Gorczak, unpublished) and more are certain to be discovered. Names listed as synonyms of *Pyxidiophora* in MycoBank (2020) are based on all three life cycle states of *Pyxidiophora* (see below).

Taxonomy and Phylogeny

Pyxidiophora was described by Brefeld and Von Tavel (1891), and its complicated nomenclatural history discussed by Lundqvist (1980) resulted in typification with *Pyxidiophora asterophora*. Both MycoBank (2020) and Index Fungorum (2020), however, list *P. nyctalidis* as the type species, likely because of recent retroactive changes in the *International Code of Nomenclature for algae, fungi, and plants* (Turland *et al.*, 2018). The gradual maturation of the perithecium and its ephemeral nature, slow ascospore maturation, difficulty of cultivation, and the complex three-morph life history of these fungi, hampered the use of morphological characters. For example, the early deliquescent asci lead some researchers to describe *Pyxidiophora* perithecia as pycnidia (e.g., *Mycorhynchus*) (Petch, 1936). These problems have caused creation of many synonyms based on the three different morphs (perithecial, hyphal phialidic conidial, and ascospore-derived dispersal morphs) in the life cycle.

Genera based on the perithecial morph are considered synonyms of *Pyxidiophora*, often based on immature specimens: *Ascolanthanus*, *Coprophilous*, *Mycorhynchus*, *Rhynchonectria*, *Treleasia* (Hawksworth and Webster, 1977; Lundqvist, 1980), and perhaps the cleistothecial *Mycorhynchidium*. The type of *Treleasia* is no longer intact, but Spegazzini's drawing of the ascospores and perithecial neck (Arambari *et al.*, 2007) leave no doubt of the identity of a species from an unusual habitat: rolled, deteriorating leaves of sugar cane. Named phialidic conidial morphs derived from hyphae include *Chalara*-like, *Gabarnaudia*-like, *Gliocephalis*, and *Pleurocatena* (Arnaud, 1952, 1953; Blackwell and Malloch, 1989b; Jacobs *et al.*, 2005; Gams and Arnold, 2007). No perithecial state is known for *Gliocephalis hyalina* (Jacobs *et al.*, 2005), but an SSU rDNA sequence places it in *Pyxidiophora*, and culture attempts of this fungus were successful only when co-inoculated with *Fusarium* as expected of a mycoparasite (Corlett, 1986). Other synonyms are based on the dispersal morph developed from the ascospore: *Acariniola*, *Thaxteriola*, and perhaps other ascospore-derived forms (Blackwell, 1994). The presumptive ascospore derived morphs including *Amphoropsis*, *Endosporella*, *Entomocosma*, *Myriapodophila*, and *Thaxteriola* spp. were placed in an informal group, "Thaxteriolae," although this name has not been defined consistently (Thaxter, 1914, 1920; Spegazzini, 1918; Majewski and Wiśniewski, 1978; Blackwell, 1994; Blackwell *et al.*, 2020). Gäumann (in Gäumann and Dodge, 1928) "regarded" some of these forms as male thalli of Laboulbeniales, an idea rejected by Thaxter (Gäumann and Dodge, 1928).

The ordinal placement of *Pyxidiophora* was uncertain until DNA analyses became available. Most often it was placed in the order Hypocreales (e.g., Lundqvist, 1980; Barr, 1990) or considered a member of the order Ophiostomatales (von Arx and van der Walt, 1987; Eriksson and Hawksworth, 1989; Blackwell and Spatafora, 1994). Based on a primarily speculative review (Blackwell and Malloch, 1989b), Eriksson and Hawksworth (1993), placed *Pyxidiophora* in the Laboulbeniales. Soon after, with increased taxon sampling, the higher-level classification of Pyxidiophorales (P.F. Cannon in Kirk *et al.*, 2001) was formally established in the family Pyxidiophoraceae (Arnold, 1971). If they exist, closer relatives of the class Laboulbeniomyces other than Sordariomyces among Ascomycota have not been discovered (Blackwell *et al.*, 2020).

Morphology of Pyxidiophorales Life Cycle States

The three-morph life cycle of *Pyxidiophora* described above with its specialized dispersal morph, is unique among Ascomycota (Fig. 5). It has been compared to the life cycles of plant-parasitic rust fungi (Basidiomycota) with respect to Tranzschel's law in its host associations (Malloch, 1995; Blackwell *et al.*, 2020).

Perithecial morphs

Ascocarps of *Pyxidiophora* are perithecia (Fig. 4C,D). One species, *Mycorhynchidium saccatum*, was described as cleistothecial from a moist chamber development (Malloch and Cain, 1971). The pseudoparenchymatous perithecia usually have a distinct bulbous base with irregularly angular to globose cells and tapers slowly to an elongating neck composed of parallel, closely packed cells (Hawksworth and Webster, 1977; Lundqvist, 1980; Kirschner, 2003; Doveri and Coué, 2006). A unique feature of the mature perithecial peridium is that it is composed of a single layer of cells. This unusual character is known only in species of *Kathistes* among other perithecial ascomycetes (Malloch and Blackwell, 1990). Interascal tissues (e.g., paraphyses) have not been observed in any species of *Pyxidiophora*. The presence of an apical ring may be ephemeral and Lundqvist (1980) does not consider it a generic character. Perithecia can be single or grouped, free on the substrate or developed on a stroma, hairy or naked, and short to very long necked. Unlike thallus-forming Laboulbeniomyces,

cell-by-cell development of fruiting bodies of Pyxidiophorales is not known in detail but likely is not fixed as in Herpomycetales and Laboulbeniales. Asci are not reported for all species because of their early evanescence (Hawksworth and Webster, 1977; Lundqvist, 1980). Production of ascocarps in pure culture was reported for *Pleurocatena acicularis* (Gams and Arnold, 2007) and in mixed cultures for *Pyxidiophora* [as *Ascolanthanus*] *trispurus* (Cailleux, 1967), *Pyxidiophora asterophora* (Brefeld and Von Tavel, 1891), *P. corallisetosa* (Kirschner, 2003), and others (M. Blackwell, unpublished).

Asci of *Pyxidiophora* are unitunicate, thin-walled, non-amyloid and fusiform, clavate or obovoid. The number of ascospores per ascus is 3–8. The common condition of three ascospores per ascus in this genus is unusual among ascomycetes. Viewed with transmission electron microscopy, 3-spored asci appear to be due to exclusion of one of four post-meiotic nuclei from the enveloping membrane system during ascosporangogenesis (M. Blackwell and E.A. Richardson, unpublished); details are not known. Asci mature sequentially and the ascospores are released passively in a sticky droplet hanging at the tip of the perithecium, awaiting an arthropod for dispersal (Breton and Faurel, 1967; Blackwell, 1994). Ascospores are two-celled, single-septate, usually symmetrical, and enveloped in a mucilaginous sheath before maturity (Lundqvist, 1980; Blackwell and Malloch, 1989a; Blackwell *et al.*, 1989). At maturity, ascospores of *Pyxidiophora* are single-septate, elongated, and fusiform to subclavate. For all species that have been observed at maturity, ascospores have a darkened attachment apparatus at their exiting ends by the time they exit the

perithecium. This is one of the inconsistent features in species descriptions, resulting from the observation of immature material (Blackwell, 1994).

Phialidic conidial hyphal morphs

A number of different conidial states arise from the hyphae, and these were described in connection with *Pyxidiophora* (Lundqvist, 1980; Gams and Arnold, 2007). The conidia of *Pyxidiophora* are blunt-ended or bullet-shaped conidia, often in chains. Arthric anamorphs probably were inaccurately mistaken for chains of conidia (Cailleux, 1967). The holoblastic conidia are produced in phialides on the mycelium. Most have been described as *Chalara*-like (e.g., in *P. asterophora*, *P. spinuliformis*) or *Gabarnaudia*-like (e.g., in *P. corallisetosa*, *P. cuniculicola*). *Pleurocatena*, first observed in the early 1950s (Arnaud, 1952, 1953; Arambarri *et al.*, 1981), was studied again in culture by Gams and Arnold (2007) with the new strains described as *Gabarnaudia*-like, although living cultures were not maintained. The authors distinguished the conidial state on the presence of setae mixed among the phialides. They connected the conidial state to *Pyxidiophora* sp. when perithecia were developed in a culture of *Pleurocatena acicularis* after several months. Other hyphal forms, probably also with phialidic conidia have been described, including *Gliocephalis hyalina* for which no perithecial state is known (Jacobs *et al.*, 2005). *Pyxidiophora spinulorostrata* was described as having heavily walled outgrowths near the perithecial necks that produced conidia (Webster and Hawksworth, 1986). Perithecia of the same species from the type locality (River Teign, Devon), however, did not produce such conidiophores; instead, a *Gabarnaudia*-like anamorph was observed before appearance of perithecia (M. Blackwell, unpublished).

Ascospore-derived conidial morphs

The second type of conidial morph in the three-morph life cycle develops from an ascospore (Fig. 4E–H). Although the entire life cycle has not been studied in all species, the ascospore-derived form occurs consistently in the best studied species of *Pyxidiophora*. Germination by germ tube has been observed on agar but rarely. Most of the ascospore-developed morphs have been referred to as *Thaxteriola* or *Acariniola*. The ascospores have gelatinous mucus sheaths early in ascospore maturation. The dark-pigmented attachment apparatus develops at the exiting end of the ascospores by the time they are released in a sticky droplet at the tip of the perithecial until disperser contact. In at least five observed species of *Pyxidiophora* the primary dispersers were phoretic mites. TEM revealed the basal cell apparatus had a system of channels with an electron-dense material that were proposed to secrete a presumptive “glue” to attach the cell to the phoretic mite (Fig. 4H; Blackwell, 1994). After attachment of an ascospore to the

phoretic mite disperser, conidium development began (Fig. 4E). Ascospores of one strain were examined for up to a week under glass cover slips on agar. Yeast cells budded from the conidia, and within 24 h, several rounds of yeast cells had been produced and the yeast cells developed germ tubes several days later (Blackwell and Malloch, 1989b). Unless a fungal host was available, there was no further development in that strain.

As mentioned above, a number of minute fungi described from insects have been suggested to be conidial morphs of *Pyxidiophora* (Blackwell, 1994). The genera *Amphoropsis*, *Endosporella*, *Entomocosma*, *Myriapodophila*, and *Endosporella*, were described by Spegazzini (1918) and Thaxter (1920). Spegazzini suggested grouping a number of these minute fungi in the “Thaxteriidae” but Thaxter (1920: 15) doubted whether “these uninteresting little plants” were closely related to each other (see Blackwell *et al.*, 1986b, 2020; Blackwell, 1994). After *Acariniola* was described (Majewski and Wiśniewski, 1978), Lundqvist (1980) placed that genus in synonymy with *Pyxidiophora*.

Fine-Tuned Life Histories

The life history of *Pyxidiophora* spp. is a fine-tuned association of a variety of organisms. Accumulating evidence from axenic culture attempts has led to the conclusion that most species of *Pyxidiophora* are mycoparasitic or at least they grow better in two-membered culture with appropriate fungi (Corlett, 1986; Webster and Hawksworth, 1986; Blackwell and Malloch, 1989b; Kirschner, 2003; Jacobs *et al.*, 2005). Some species of *Pyxidiophora* were once considered saprotrophs (Lundqvist, 1980), and difficulties in obtaining axenic cultures led to earlier assumptions of nematophagous or bacteria-dependent modes of nutrition (Cailleux, 1967). The superb light and transmission electron micrographs of *Gliocephalis hyalina* (Jacobs *et al.*, 2005) provided strong evidence of contact mycoparasitism. It should be noted that two strains of *Pyxidiophora arvernensis* (CBS 657.82, CBS 253.81) isolated from *Rhizoctonia solani* baits in soil, have been used for DNA sequencing, because they do grow, albeit poorly, in axenic culture (Schoch *et al.*, 2012).

Timing is essential to the closely associated assemblage of organisms. For example, species on dung substrates use fungal hosts that arrive with the dung substrate by gut passage (Blackwell and Malloch, 1989b). Potential fungal hosts for *Pyxidiophora* spp. on seaweed probably arrive on the beach already growing in the seaweed, ready to nourish *Pyxidiophora* conidial morphs dispersed by arthropods on the beach (M. Blackwell and D. Malloch, unpublished). Kirschner (2003) pointed out that *P. corallisetosa* and *P. cuniculicola* and their fungal hosts were dispersed together by arthropods. *Pleurocatena acicularis*, a *Pyxidiophora* hyphal conidial state, was baited with fungi from soil (Gams and Arnold, 2007). The actual host of *P. asterophora*, observed on the mushroom of *Asterophora lycoperdoides* (Agaricales, Agaricomycetes), is unclear. *Asterophora* spp. are parasites of other mushrooms (*Lactarius* and *Russula* species), and an assemblage of organisms is present on the *Asterophora* mushrooms, including a tremellaceous yeast (Prillinger *et al.*, 2007) and fungi and bacteria developed in age (M. Blackwell, unpublished). The actual host of *Pyxidiophora asterophora*, therefore, remains unknown, but it may not be the mushroom. Buller (1924) suggested air dispersal of *Asterophora* chlamydospores and, although scarce in some of the mushrooms, basidiospores. Because the timing of arrival and dispersal is essential in the life history, it would be informative to know if these events occur consistently.

Documented fungal hosts used by *Pyxidiophora* include *Ascobolus* sp. (Pezizales, Pezizomycetes) growing on moose dung for *Pyxidiophora* sp. (Fig. 6A; Haelewaters, 2014), *Clonostachys rosea* (Hypocreales) for *P. corallisetosa*, *Esteya vermicola* (Pezizomycotina incertae sedis) for *P. cuniculicola* (Kirschner, 2003), *Fusarium poae* (Hypocreales) on seeds of *Triticum aestivum* for *P. lundqvistii* (Corlett, 1986), *Neonectria lugdunensis* (Hypocreales, Sordariomycetes) for *Pyxidiophora spinulorostrata* (Webster and

Fig. 6 Substrates for *Pyxidiophora*. **A.** Moose dung with apothecia of *Ascobolus* sp., from which perithecia of *Pyxidiophora* were isolated (White Mountain National Forest, Maine, USA). **B.** Perithecium of *P. corallisetosa* with package of ascospores at the tip (arrowhead), from a gallery of *Ips typographus*, the European spruce bark beetle, in Norway spruce (Białowieża Primeval Forest, Poland).

Hawksworth, 1986), and apothecia of coprophilous Pezizales for *Pyxidiophora* sp. and *P. spinuliformis* (Blackwell and Malloch, 1989b). Specificity of the fungal hosts of *Pyxidiophora* has not been studied in detail but has been noted (Corlett, 1986; M. Blackwell and D. Malloch, unpublished).

Blackwell and Malloch (1989b) studied the life histories of *Pyxidiophora* sp. and *Pyxidiophora spinuliformis* from moose dung in Algonquin Park, Ontario, Canada, and gathered data on timing of those species. The study was conducted by leaving the major part of a dung pile in the field for daily comparison with portions of the same substrate in moist chamber in the laboratory. On the day of deposition, the dung had no surface growth noticeable to the eye. The first appearance of *Pyxidiophora* sp. occurred after 5–7 days when synnemata of the hyaline *Chalara*-like conidial state (Fig. 4A,B) developed, clustered on the apothecium of a host fungus. Maximum conidium viability at seven days corresponded with rapid movements by immature nematodes and fungus-feeding and predaceous mites that apparently spread the conidia on the dung surface; the nematodes may be food for the mites. A week after dung deposition, perithecia developed in the vicinity of the synnemata, often growing through the synnemata. Ascospores matured rather slowly beginning within the ascus and continuing after ascus evanescence and ascospores were released passively to the perithecial tip. Ascospores were transported by predaceous mites 1–3 days after ascospore release (Fig. 4F). The second species, *P. spinuliformis*, developed more slowly compared to *Pyxidiophora* sp., with the hyphal conidial state of *P. spinuliformis* appearing 12–15 days after appearance of *Pyxidiophora* sp., and perithecia developing 3–4 days later on the same apothecia. Passive ascospore release to the perithecial tip corresponded in time with maturation of a different mite. Ascospore maturation coincided precisely with mite maturation judged by the number of attached ascospores compared.

The timing of life cycles of species on substrates other than dung is not well known. One example, *P. spinulorostrata*, has a longer incubation period than species growing on ephemeral substrates. With the help of John Webster, twigs were collected from the River Teign in Devon, England, the type locality of the species, and mailed to Baton Rouge, Louisiana, USA, where they were incubated in plastic containers at room temperature for observation (M. Blackwell, unpublished). About a month after collection, *Gabardnaudia*-like conidia developed, and about 7 days later, *P. spinulorostrata* perithecia appeared in association with *Heliscus lugdunensis*. No additional information, especially on potential vectors, is available. Conidia were not observed on the perithecial outgrowths as had been described (Webster and Hawksworth, 1986).

In addition to the need for a host, a second requirement for *Pyxidiophora* life cycle completion is escape from a depleted substrate. Insects, often beetles, are essential for targeted dispersal of the ascospore-derived morphs. Mites, however, may be of vital importance (Blackwell *et al.*, 1986a, 1986b, 1989). For example, *Pyxidiophora corallisetosa* and *P. kimbroughi* grow in the secondary phloem in bark beetle galleries (Fig. 6B). Bark beetles, however, mature in the outer bark of the tree requiring phoretic mites to transport the ascospores to the beetle vector. On substrates that can be observed, mites are more plentiful than beetles and they become very active, almost frantic in human terms, in moist chamber cultures coinciding with time of ascospore maturation (Blackwell *et al.*, 1986a; Blackwell and Malloch, 1989b).

Expanding Diversity

Easily discovered species of *Pyxidiophora* perithecial morphs have come from exposed substrates with abundant flying insects and phoretic mites. These include herbivore dung, fleshy fungi, beetle galleries in wood, decaying plant material, and beached seaweed known as wrack (Blackwell and Malloch, 1989a). Species occurring in bark beetle galleries, sometimes have been detected by observing the ascospore-derived conidial states on mites (Blackwell *et al.*, 1989). In fact, the wrack habitat was discovered by finding the ascospore-derived conidial state (*Thaxteriella*) attached to mites from wrack in the Natural History Museum, London. Unlike looking for a needle in a haystack, once a fertile habitat is discovered, *Pyxidiophora* species usually can be recollected. Some species have been discovered in BLAST searches of nucleotide databases. For example, the ITS sequence of *Pyxidiophora arvernensis* (CBS:657.82, GenBank accession number MH861535) was a close match with NCBI GenBank (accession number MF484620), “an uncultured Glomerales soil isolate.” Is the sequence that of an arbuscular mycorrhizal (AM) fungus or is it more likely that of a *Pyxidiophora* using the AM fungus as a host? Several environmental ITS sequences from GenBank (see “Relevant Websites section”), the UNITE database (Abarenkov *et al.*, 2010), and Tedersoo *et al.* (2014) share ≥95% identity with sequences of known Pyxidiophorales (Fig. 7).

Laboulbeniopsis Clade

Laboulbeniopsis termitaria is an ectoparasite of termites, described from specimens collected in Grenada (Thaxter, 1920). The species was re-discovered fifty years later and is now known from Florida (Kimbrough and Gouger, 1970; Blackwell and Kimbrough, 1976b), Georgia (Blackwell, 1980a,b), Louisiana (Henk *et al.*, 2003), and Japan (Guswenrivo *et al.*, 2018). The minute thalli are under 150 µm in size and usually comprised of four superposed cells. The basal cell has a system of channels that secrete what is apparently a glue-like material attaching the thallus to the termite. This basal cell also contains a darkened pad, which seems diagnostic for *Laboulbeniopsis*. The elongated, and often brown in age distal-most cell produces spores at its base, which have been suggested to be ascospores. In fact, the attachment apparatus is almost identical with that of *Pyxidiophora* (see above) and *Coreomycetopsis* (see below). The presumptive asci evanesce and the presumptive ascospores are released through an apical ring at the thallus tip (Blackwell and Kimbrough, 1976b).

Fig. 7 Diversity of environmental ITS sequences of Pyxidiophorales. The topology is the result of maximum likelihood inference using RAxML (Stamatakis, 2014). Colored circles indicate geographic origin, black symbols indicate isolation source, sequences highlighted in green are known representatives of the order Pyxidiophorales.

An SSU rDNA phylogeny resulted in placed *Laboulbeniopsis* in the Laboulbeniomyces with strong support (Henk *et al.*, 2003). Its placement was previously unknown even though it had been suggested to be associated with Laboulbeniomyces based on morphology. More recently, Blackwell *et al.* (2020) found strong support for the sister relationship of *Laboulbeniopsis* and Pyxidiophorales in a two-locus rDNA phylogeny. The phylogeny revealed high support for five clades in the Laboulbeniomyces: the orders Herpomycetales, Laboulbeniales, and Pyxidiophorales, and in addition the *Laboulbeniopsis* clade and the *Chantransiopsis* clade (Fig. 1D).

Coreomycetopsis oedipus, another minute fungus known only from termites, is placed in this clade based upon its morphological similarity to *Laboulbeniopsis*. The typical thallus of *C. oedipus* is under 150 µm in size and consists of fewer than fifteen superposed cells. Based on a report by Blackwell and Kimbrough (1976a), eight of the distal-most cells are obliterated by upward growth of thin filaments in the development of a “sporogonium.” Some of the filaments developed as phialides and produced elongated phialospores. *Coreomycetopsis oedipus* is less often collected than *Laboulbeniopsis termitaria*, and although it may be less common, it is more difficult to discern against the pale termites because it has no dark pigments. It was described from Grenada (Thaxter, 1920) and since then recorded, in Florida (Blackwell and Kimbrough, 1976a), Georgia and Louisiana (M. Blackwell, unpublished), and Panama (D. Haelewaters, unpublished). Several mycologists suggested that *Coreomycetopsis* and *Laboulbeniopsis* may be different conditions or states of the same fungus, but morphological data are not supportive of this hypothesis (Blackwell and Kimbrough, 1976a,b). As already noted, at the ultrastructural level, the attachment region of *Laboulbeniopsis termitaria* and *C. oedipus* and *Pyxidiophora* are identical, though *Coreomycetopsis* lacks the darkened pad present in *Laboulbeniopsis*. Additionally, the terminal cells of the *Coreomycetopsis* thallus are thought to form a cavity where phialospores develop; a similar cavity in *Laboulbeniopsis* thalli is reported to produce ascospores in an evanescent ascus (Blackwell and Kimbrough, 1976b). The ultrastructural studies describing reproductive structures in these two termite-associated fungi need confirmation.

Chantransiopsis Clade

The *Chantransiopsis* clade comprises two conidial fungi known only as insect ectoparasites, *Chantransiopsis* and *Tetrameronycha* (Fig. 1D; Thaxter, 1914, 1920; Spegazzini, 1918; Rossi and Blackwell, 1990). Not much is known about these genera, other than their sparse filamentous growth occurs on insects. The other member of this clade is *Subbaromyces splendens*, a perithecial ascomycete with a distinctive collar-like structure at the base of the long perithecial neck, giving the perithecial the look of an injection syringe. *Subbaromyces splendens* was discovered on rocks in trickling sewage filter beds in New York, USA (Hesseltine, 1953). A second morphologically and ecologically similar species, *S. aquaticus*, was isolated from an open drain in Hyderabad, India (Manoharachary and Ramarao, 1974). Both species have limited growth in culture but produce conidia; production of perithecial and ascospores occurs only in mixed cultures. As with *Pyxidiophora*, these related fungi appear to have some dependence on other fungi, and perhaps are mycoparasites.

The genera *Chantransiopsis* and *Tetrameronycha* were for the first time included in the Laboulbeniomyces by Goldmann and Weir (2018) in their SSU rDNA phylogenetic reconstruction of class members (Fig. 1B). Both genera were placed in a maximally supported clade in the phylogenetic reconstruction by Blackwell et al. (2020), presenting evidence for at least two clades with conidial states (*Chantransiopsis* clade, Pyxidiophorales) (Fig. 1D). Blackwell et al. (2020) generated sequences of *S. splendens* from a Hesseltine (1953) culture (CBS:357.53) and found high support for a placement among *Chantransiopsis* and *Tetrameronycha*. The inclusion of *Subbaromyces* in Laboulbeniomyces was perhaps surprising, but the long-necked perithecia, evanescent asci, and accumulation of ascospores at the tip of perithecia are characteristic of other members of the class and suggests dispersal by arthropods.

Filling Knowledge Gaps

We close our discussion of the 170-year story of the Laboulbeniomyces by pointing out missing chapters and pages. The basic outline for telling the complete story is a stable, well-resolved phylogeny that places these fungi within the rest of the ascomycetes; while we know that the Laboulbeniomyces and Sordariomyces form a monophyletic clade in the *Ascomycota Tree of Life*, the direct sister group of the Laboulbeniomyces remains to be discovered. Progress in developing evolutionary hypotheses of the group will depend on (1) sampling new specimens, (2) studying the ecology, and (3) using multiple molecular markers and phylogenomic approaches.

Sampling new specimens of fungi associated as ectoparasites of arthropods but also free-living arthropod-dispersed fungi is crucial to obtain a complete picture of the diversity that is present in the class. Known host groups should continue to be investigated for the presence of Laboulbeniomyces by both collecting in the field and screening museum collections. Existing literature will remain essential to point out hosts and localities in these endeavors. Priority should be given to those host species from which types have been described. Once infected specimens are found, sequences must be generated to define species limits and describe within-species phenotypic plasticity. In fact, not understanding the extent of morphological variation, obscures our conclusions concerning host shifting, specificity, and cryptic diversity.

Ecological aspects of Laboulbeniomyces remain understudied. Climate effects on the distribution and survival of Laboulbeniomyces and their hosts are poorly known. Focusing on ant- and bat fly-associated Laboulbeniales across Europe, Szentiványi et al. (2019) found that localities with low annual mean temperature and humidity, the likelihood of Laboulbeniales presence is higher. Welch et al. (2001) reported a prevalence of *Hesperomyces virescens* on *Adalia bipunctata* ladybirds as high as 54.7% in London, whereas prevalence had decreased to 0% at 25 km outside of the city. This extreme, short-range variation in prevalence was attributed to host phenology; the “urban heat island effect” shortens winters and may promote aphid growth – as do car pollution and urbanization. These factors increase host survival and enhance inter-generational contacts between ladybirds, providing ample opportunities for transmission of *H. virescens* (Welch et al., 2001). Although these two examples seem to be

contradictory at first sight (lower versus higher temperature promoting development of Laboulbeniales), this illustrates that different Laboulbeniales may have different environmental preferences. More data are necessary from more parasite–host systems and larger geographical areas to pinpoint general patterns. A genomics approach has been used in a somewhat similar situation to look at fungal range extensions by detecting genome-wide differences in strains of the fungi involved that were associated with certain temperature and precipitation conditions across the range (Galagan *et al.*, 2005; Smith *et al.*, 2019).

Multiple molecular markers are already being applied to increase phylogenetic resolution and to discover additional members of the class among newly collected specimens. A significant milestone in Laboulbeniomyces research, however, has been the acquisition of a 15-Mb draft genome sequence assembly of *Herpomyces periplanetae* (Haelewaters *et al.*, 2020b). An increasing number of reviews and research papers describe the use of genomics and proteomics applied to fungal mutualists (Biedermann and Vega, 2020) and pathogens of insects (Wang and Wang, 2017). Genome-scale data offer a short-cut to answering many questions, essentially turning any of the Laboulbeniomyces into model fungi well suited for studies of symbiosis tracking interactions of fungi and their arthropod hosts.

Genomics will soon be used to predict reciprocal interactions of Laboulbeniomyces and their associates. For example, basic questions about the *mode of nutrition*, can be addressed by an approach referred to as reverse ecology (Ellison *et al.*, 2011). In a study of endophytes of rubber trees, enzyme profiles were evidence of an unexpected insect-association rather than the expected plant-associated profile similar to that of the Xylariales (Gazis *et al.*, 2016). Correlations of variation in nutrition over parts of geographic ranges of broadly distributed species with genome changes (e.g., gene family expansions and enzyme family diversification) (Qian and Zhang, 2014), identification of genes unique to fungus–insect symbiosis (Wang *et al.*, 2018), and discovery of recurrent symbiont replacements by entomopathogenic fungi (Matsuura *et al.*, 2018), are the type of studies that will inform interactions among Laboulbeniomyces and their associates. Are there other interactions, for example, signaling among Laboulbeniomyces and loosely associated organisms (Becher *et al.*, 2018)? The tight associations suggest the possibility of horizontal gene transfer of siderophores found in microbe-packed insect guts (Tabima *et al.*, 2020).

Several species of Laboulbeniales and Herpomycetales occur on a *diverse variety of hosts* and have extremely *wide distribution ranges*, from subboreal to tropical areas. Molecular phylogenetic analysis and sequence-based species delimitation methods are necessary to evaluate whether these taxa are effectively ubiquitous, that is, capable of thriving on a wide range of hosts in many different microhabitats and climates, or whether they belong to separate cryptic or near-cryptic species. Examples are a number of taxa in *Laboulbenia*. One of the most widespread and most commonly sampled species is *L. flagellata*. Since its description (Peyritsch, 1873), it has been reported from more than 80 genera of Carabidae in many countries on all continents except Antarctica (Santamaría *et al.*, 1991; Majewski, 1994). Based on a limited LSU rDNA dataset, Haelewaters and De Kesel (2020) revealed three clades of *L. flagellata* *sensu lato*. It goes without saying that a lot more work will be needed to resolve the taxonomy of this and other species complexes. Genome comparisons have shown that variation occurs across taxa with broad distributions and have helped to identify genomic factors involved in adaptation in parts of the range (Galagan *et al.*, 2005; Smith *et al.*, 2019; Mei *et al.*, 2020).

Epilogue

Harkening back to the beginning of this chapter, the section “From Roland Thaxter to the Present: Synergy Among Mycologists, Entomologists, Parasitologists”, and the mention of reviews at fifty-year intervals (Benjamin, 1971; Haelewaters *et al.*, 2021c), we anticipate a next comprehensive review – but likely many years before 2071. Major achievements in the taxonomy and systematics of Herpomycetales, Laboulbeniales, Pyxidiophorales, and related arthropod-associated fungi will be accomplished, but so much else can be discovered. We expect that significant progress based on molecular phylogenetic and phylogenomic studies, but also new collections, will speed the effort. But, who will there be write it? Perhaps a young student who is reading this chapter now.

Acknowledgments

D.H. acknowledges previous and current support from the Mycological Society of America, Smithsonian Tropical Research Institute, Horizon 2020 Research Infrastructures Program of the European Union (SYNTHESIS+ grant BE-TAF-151), and Research Foundation – Flanders (junior postdoctoral fellowship 1206620N). M.G. was supported by the Polish Ministry of Science and Higher Education (grant DI2014012344). P.K. was funded by a Josiah Lowe and Hugh Wilcox scholarship during her graduate program at the Department of Environmental and Forest Biology (SUNY-ESF). M.B. acknowledges previous funding from the National Science Foundation (grants BSR-8604656, NSF BSR-8918157, NSF DEB-9208027, NSF DEB-9615520) and the Louisiana State University Boyd Professor Research Fund. She also thanks the Radcliffe Institute for Advanced Study at Harvard University for an intellectual environment and proximity to the unsurpassed resources of the Farlow Reference Library and Herbarium of Cryptogamic Botany. We acknowledge the helpful nomenclatural advice of Paul Kirk given late on a Sunday evening. A shout-out to postgraduate research assistant Jingyu Liu (Purdue University, Department of Botany and Plant Pathology, M. Catherine Aime Lab) for her amazing talent to make line and stipple drawings of these (and other) fungi. We are especially grateful to our mentors and colleagues who have made significant contributions to the world of Laboulbeniomyces: Richard K. Benjamin, Lauren M. Goldmann, James W. Kimbrough, Tomasz Majewski, David Malloch, John C. Moser, Thelma J. Perry, Donald H. Pfister, Walter P.

Pfliegler, Ana Sofia P.S. Reboleira, Walter Rossi, Sergi Santamaría, Isabelle I. Tavares, Rosa V. Villarreal Saucedo, and Alex Weir. And finally, where would we be without Cybertruffle, Index Fungorum, Index Herbariorum, museum collections, MycoBank, MyCoPortal, and the NCBI GenBank?

Phylogenetic Advances in Leotiomyces, an Understudied Clade of Taxonomically and Ecologically Diverse Fungi

C Alisha Quandt, University of Colorado, Boulder, CO, United States

Danny Haelewaters, Purdue University, West Lafayette, IN, United States; Ghent University, Ghent, Belgium; Universidad Autónoma de Chiriquí, David, Panama; and University of South Bohemia, České Budějovice, Czech Republic

Introduction

The class Leotiomyces represents a large, diverse group of Pezizomycotina, Ascomycota (LoBuglio and Pfister, 2010; Johnston *et al.*, 2019) encompassing 6440 described species across 53 families and 630 genera (Table 1). Comprising, among other morphologies, the inoperculate discomycetes, Leotiomyces fungi represent an enormous amount of ecological diversity – including mutualists and pathogens of plants, saprotrophs, animal pathogens, et cetera. Owing at least partially to their small size or the absence of a fruiting body, Leotiomyces fungi are often overlooked in the field, in the mycology classroom, and in community ecology studies. The major challenges that currently exist in studying Leotiomyces include a lack of understanding about (1) the subclass-level relationships within this clade, (2) the diversity of taxa that are exclusively detected by environmental DNA studies, and (3) the functional roles of such undescribed taxa in the environment.

Morphological and Ecological Diversity of Leotiomyces

Morphology

Many Leotiomyces that form sexual fruiting bodies have various forms of small apothecia with exposed hymenia as well as inoperculate asci – hence the historical grouping to which many Leotiomyces belonged, the *inoperculate discomycetes* (Eriksson, 2005). The asci of Leotiomyces taxa do not possess a lid-like structure (operculum); ascospores are extruded through an amyloid apical ring or by the asci splitting open apically (in which case they are inamyloid). Variations of the typical apothecium morphology exist within the class including those that remain closed until maturity as seen in several orders including Lahmiales and Rhytismatales. Other types of sexual fruiting bodies include the permanently closed cleistothecia, produced by *Cleistothelobolus*, *Leptokalpion*, *Thelebolus* (Thelebolales); *Bicornispora* (Rutstroemiaceae), *Connersia*, *Pleuroascus* (Helotiaceae), and members of Amorphothecaceae, Erysiphaceae, and Myxotrichaceae (Helotiales).

Several lineages are amenable to growth in axenic culture. Asexual reproduction is commonly observed in Leotiomyces, with some taxa that are exclusively known from their asexual forms (e.g., Castañeda-Ruiz and Kendrick, 1990; Palmer *et al.*, 2014; Ashrafi *et al.*, 2018). Johnston *et al.* (2014) made nomenclatural recommendations to reconcile genera where both sexual and asexual morphs were independently named.

Ecology

Known ecologies from this clade are highly diverse, but Leotiomyces are most commonly known in association with plants either as saprotrophs on already dead material (Baral and Haelewaters, 2015; Hernández-Restrepo *et al.*, 2017; Haelewaters *et al.*, 2018b), endophytes of roots, leaves, bark (Griffith and Boddy 1990; Rodriguez *et al.*, 2009; Grünig *et al.*, 2011), mycorrhizae (Cairney, 2006), or pathogens of roots, shoots, and leaves (Glawe, 2008; Saharan and Mehta, 2008). The plant pathogens in this class are of considerable economic importance – including the powdery mildews of cucurbits and other food crops and the white mold, *Sclerotinia*, that can infect at least 408 species of plants at any stage of development and any tissue type. Bryophilous (or bryosymbiotic, moss-associated) taxa exist as well (Döbbeler, 1997; Stenroos *et al.*, 2010). Examples are members of *Bryoscyphus* and *Mniaecia*, which are biotrophic parasites. Many Leotiomyces are ecologically classified as aquatic hyphomycetes, which decay various plant material in freshwater ecosystems (Baschien *et al.*, 2013).

Taxa not associated with plants are also well represented throughout the class. These include the recently described *Polyphilus*, a genus associated with nematodes, truffle fungi, and plant roots (Ashrafi *et al.*, 2018). Other species associated with animals are species of *Pseudogymnoascus* such as *P. destructans* (the causal agent of white-nose syndrome in bats) (Gargas *et al.*, 2009) and *P. pannorum* (a pathogen of humans) (Gianni *et al.*, 2003). There are many so-called lichenicolous taxa (e.g., *Epicladonia*), which fruit epiphytically on lichens, and the newly described lichen-forming leotiomycete, *Lichinodium* (Prieto *et al.*, 2019). In addition, one species of *Trochila* is a potential mycoparasite on rusts (Gómez-Zapata *et al.*, 2021). Like many fungi in Ascomycota, Leotiomyces are important producers of secondary metabolites (Vaca and Chavez, 2019), including *Glarea*, which makes pneumocandin B – the precursor to one of the most potent antifungal drugs, Caspofungin B (Chen *et al.*, 2013). Yet many isolated Leotiomyces, such as *Glarea*, still have unknown ecological roles.

Current Understanding of Evolutionary Relationships

Challenges of Leotiomyces Systematics

Ascomycota is the largest phylum of fungi and among the best studied ones. As a consequence, one might assume that the diversity and systematics within this large and ubiquitous clade is well understood, and for most of its classes this is largely true. However, Leotiomyces have suffered from several issues that have impeded systematics of the class, such that its classification is one of the most poorly understood of any fungal clade. Marker loci designated for the large-scale Assembling Fungal Tree of Life project (AFTOL) (Spatafora *et al.*, 2006), which have been successful for most fungal lineages, result in conflicting and unsupported relationships within Leotiomyces. These markers also suggest that traditional morphological characteristics are uninformative in discerning even family-level relationships (Wang *et al.*, 2006b; LoBuglio and Pfister, 2010; Zhang and Wang, 2015; Baral, 2016). Indeed, since molecular characters have become available, the classification of Leotiomyces has undergone multiple drastic updates. However, if there is something that has been consistent among all phylogenetic reconstructions of the class thus far, it is the presence of polytomies, polyphyletic higher taxa, and long branches. Even today, evolutionary hypotheses about family- and order-level relationships are being inferred using a single locus or few uninformative loci, and many taxa have no molecular data at all.

Whole-genome sequences for plant-pathogenic Leotiomyces such as *Botrytis cinerea* and *Sclerotinia sclerotiorum* were first published nearly a decade ago (Amselem *et al.*, 2011), but it was not until very recently that genomes were employed in Leotiomyces systematics. Johnston *et al.* (2019) provided the first evidence that genome-scale data have the potential to resolve relationships within the class, especially within the hyper-diverse order Helotiales. The authors also presented a 5–15 locus phylogeny, which still seems to conflict with the topology of genome-scale sampling (Fig. 1). Genome sampling for many clades was completely lacking, especially outside of Helotiales, which resulted in a lack of support at all deep nodes within the class (Johnston *et al.*, 2019). If genome-scale data are required for resolving the systematics of Leotiomyces, then much work is left to be done (Fig. 2).

The classification by Kirk *et al.* (2008) in the *Dictionary of Fungi* included six orders: Cyttariales, Erysiphales, Helotiales, Leotiales, Rhytismatales, and Thelebolales (with uncertainty). Baral (2016) accepted ten orders of Leotiomyces: Cyttariales, Erysiphales, Helotiales, Lahmiales, Leotiales, Medeolariales, Phacidiales, Rhytismatales, Thelebolales, Triblidiales. Since that time, several papers were published describing new orders within Leotiomyces (Crous *et al.*, 2017; Hernández-Restrepo *et al.*, 2017; Prieto *et al.*, 2019; Johnston *et al.*, 2019; Quijada *et al.*, 2020). On the other hand, Karakehian *et al.* (2019) synonymized Triblidiales under Rhytismatales, and Johnston *et al.* (2019) found support for the powdery mildews (Erysiphaceae) to be part of Helotiales. In addition, several leotiomycetous families have shifted in time from one place to another. For example, Tympanidaceae was placed in Phacidiales (Baral, 2016) but the 5–15 locus tree from Johnston *et al.* (2019) recovered the family in Leotiales with high statistical support. Both families Amorophthecaceae and Myxotrichaceae were previously considered Leotiomyces *familiae incertae sedis* but multilocus and genomic-scale phylogenetic analyses have shown that they are both placed in Helotiales (Johnston *et al.*, 2019). Myxotrichaceae is paraphyletic based on the ITS region (Seifert *et al.*, 2007). Ekanayaka *et al.* (2019) synonymized Myxotrichaceae under Amorophthecaceae but only had a single isolate of *Amorophtheca* available, which was placed sister to their Myxotrichaceae clade – highlighting the need for improved taxon sampling in addition to increased sequencing efforts.

Chaetomellales

Well-defined and distinct from other families (Baral, 2016), this group was formerly treated as family Chaetomellaceae within Helotiales. The elevation to ordinal level was based on a nuclear ribosomal RNA large subunit (LSU) phylogeny (Crous *et al.*, 2017)

Fig. 1 Current evolutionary hypotheses about interordinal relationships within the class Leotiomyces, based on Johnston *et al.* (2019). *Left*, 5–15 locus phylogeny based on 279 isolates; *right*, whole-genome scale phylogeny based on 49 isolates. Nodes where support is lacking are marked with a black “x”. Orders that are represented in *both* analyses are highlighted in color (Helotiales in yellow, Phacidiales in peach, Rhytismatales in green, Thelebolales in gray), showing major topological disagreement between the two analyses. Other orders have thus far not been considered in Leotiomyces-wide multilocus or genome-scale analyses. Modified from Johnston, P.R., Quijada, L., Smith, C.A., *et al.*, 2019. A multigene phylogeny toward a new phylogenetic classification of Leotiomyces. IMA Fungus 10, 1.

Fig. 2 Current status of sequences submitted to NCBI GenBank and published and/or publically available genomes of class Leotiomyces. Numbers of sequences were capped at 3000. A logarithmic scale is used for numbers of genera (Y axis, *right*). Note that whole-genome sampling has only been done in four orders: Helotiales (35 genomes), Phacidiales (1), Rhytismatales (6), and Thelebolales (4). Sequences are available for every order with the exception of Lahmiales.

and confirmed by the phylogenetic reconstruction of a 5–15 locus dataset (Johnston *et al.*, 2019). Apothecia of Chaetomellales are 0.2–1.0 mm in diameter, develop beneath the host epidermis, and are hairless (*Pilidium*) or covered with long setae (*Chaetomella*). The asci are 8-spored and have a thick-walled inamyloid apex. There are two distinct anamorphs (synanamorphs): sessile pycnidia that open by fissures in *Sphaerographium* and sessile or long-stalked sporodochia in *Synchaetomella*. These anamorphs can be hairless or have scattered setae. Members of Chaetomellales are parasitic or saprotrophic on leaves, herbaceous stems, and dicot fruits. Some taxa are host-specific, whereas others may have multiple hosts.

Cyttariales

Species of *Cyttaria*, the single genus in this order, are obligate biotrophic associates of *Nothofagus* trees in southern South America and southeastern Australasia (Peterson and Pfister, 2010). They produce trunk and branch cankers on their host trees. During his voyage on the *HMS Beagle*, Charles Darwin collected in Chile the golf ball-shaped fruiting bodies that would serve as type material for the first two described *Cyttaria* species (Berkeley, 1842). *Cyttaria* species are distinct from other leotiomycetous taxa by their spherical fruiting bodies of sterile stroma with numerous apothecial cavities in a honeycomb-like arrangement. Asci have an amyloid apical ring and the anamorph stage is pycnidial. Peterson *et al.* (2010) found high co-phylogenetic structure between *Cyttaria* and *Nothofagus*, even though they did not report simple one-to-one relationships. Cyttariales is apparently closely related to Helotiales. Using a four-locus phylogenetic reconstruction of a Leotiomycetes-wide dataset, Peterson and Pfister (2010) retrieved Cyttariales as sister to Cordieritidaceae, leaving the order Helotiales paraphyletic. In the concept of Helotiales sensu Johnston *et al.* (2019), Cyttariales would be a family-level clade in this mega-order, but multilocus data for *Cyttaria* is still lacking.

Helotiales

The most speciose and best studied order in the class (Table 1), initial phylogenetic work discerned that this expansive order was polyphyletic (Wang *et al.*, 2006a,b; Schoch *et al.*, 2009). Currently, a broad concept is maintained based on multilocus and genome-scale phylogenetic analyses; Helotiales sensu Johnston *et al.* (2019) also includes Cyttariaceae (pending multilocus data) and the Erysiphaceae family of powdery mildews (see Section “Helotiales, a Mega-Order in Disarray”). Helotiales fungi are mostly apothecial, with apothecia that are usually < 2 mm in diameter, sessile to long-stalked, dark to bright-colored, superficial or erumpent through the plant tissue. Some representatives form non-apothecial ascomata; *Amorphotheca* (Amorphothecaceae), *Bicornispora* (Rutstroemiaceae), *Connersia*, *Pleuroascus* (Helotiaceae), and members of Erysiphaceae and Myxotrichaceae sensu Johnston *et al.* (2019) are cleistothecial, whereas members of Loramyetaceae and *Unguicularia* (Hyaloscyphaceae) are perithecial. Most members of Helotiales are saprotrophs, decaying dead organic material, but some are associated with living organisms as either parasites, pathogens, or mutualists (Stenroos *et al.*, 2010; Baral, 2016; Haelewaters *et al.*, 2018b; Tanney and Seifert, 2020).

Lahmiales

The order Lahmiales was introduced by Eriksson (1986) to accommodate a single genus with currently two species (Species Fungorum, 2020). In 2007, the order was placed as *Pezizomycotina incertae sedis* by Hibbett *et al.* (2007), along with orders Medeolariales and Triblidiales, which we now know all belong to Leotiomycetes. Raitviir and Spooner (1994) suggested several placements for Lahmiales, in Dothideomycetes and Lecanoromycetes. Currently, still, no sequences exist but Baral (2016) suggested a placement of the order within Leotiomycetes, noting the resemblance of ascomata of *Lahmia* with Rhytismatales except the bitunicate asci and the absence of a dypeate stroma. Ascomata of *Lahmia* measure 0.13–0.30 mm in diameter, they are black, erumpent, and open at maturity by irregular radial splits. These fungi occur on the bark of *Populus* trees in boreal North America and northern Europe. The Lahmiales order is probably the least studied of leotiomycetous orders; the last described species, *Lahmia waghornii*, dates from 1900. (Note that *Lahmia plumbina* was described in 1930, but has since been recombined in the genus *Toninia*, Ramalinaceae, Lecanoromycetes.) Recent collections of Lahmiales are scarce and ambiguous, and no sequences are currently available (Fig. 2).

Lauriomycetales

This recently described order (Hernández-Restrepo *et al.*, 2017) consists of a single family with a single asexual genus, *Lauriomyces* (Castañeda-Ruiz and Kendrick, 1990), and includes 11 species (Somrithipol *et al.*, 2017). Characterized by brown conidiophores with acropetal chains of hyaline conidia, these species are only known from leaf litter and have a cosmopolitan distribution. Phylogenetic placement of Lauriomycetales suggests this is an early diverging lineage within Leotiomycetes, possibly sister to Chaetomellales (Hernández-Restrepo *et al.*, 2017; Somrithipol *et al.*, 2017) although so far this relationship is based solely on ribosomal DNA data.

Leotiales

Carpenter (1988) erected Leotiales with genus *Leotia* as its type to accommodate taxa in Helotiales. The most recent conception of Leotiales is based on Johnston *et al.*, 2019, and includes large, stipitate to clavate apothecial members of Leotiaceae (including

Leotia and *Microglossum*), stipitate to sessile apothecial taxa in Tympanidaceae s.s. and *Mniaecia*, and several aquatic hyphomycete genera. Ecological niches in this order vary from plant-pathogenic taxa such as *Tympanis* (Ouellette and Pirozynski, 1974), to the liverwort-parasitic or possibly lichenized *Mniaecia* (Raspé and de Sloover, 1998; McCune and Stone, 2020), and potentially arbutoid mycorrhizal taxa such as *Leotia* (Kühndorf et al., 2015), although some consider this genus to be saprobic.

Lichinodiales

Formerly classified in Lichinomycetes, the lichenized genus *Lichinodium* is now recognized as a member of Leotiomycetes (Prieto et al., 2019). Lichinodiales is possibly allied with Leotiales, although more sampling is needed, especially given the recent report that *Mniaecia* could be lichenized (McCune and Stone, 2020). The four recognized species of *Lichinodium* are filamentous lichens (so called because of the lack of a stratified lichen thallus) with cyanobacterial photobionts in the genus *Rhizonema* (Prieto et al., 2019). They produce gelatinous brown apothecia with indistinct margins, 0.5–1 mm in diameter, and prototunicate asci without amyloid staining. They are found on various substrates in cool, humid environments.

Marthamycetales

Erected by Johnston et al. (2019) to accommodate the single family Marthamycetaceae, these taxa are all saprobic on plant material and produce ascomata erumpent through host tissue (Minter, 2003). Asci are thin-walled and amyloid with variation in ascospore septation among the different taxa. Notable genera include *Propolis* (see Minter, 2003 for a review of species traditionally placed in this genus) and *Marthamyces* in which there has been considerable recent work describing new species (Johnston, 2006; Johnston and Park, 2019; Crous et al., 2019).

Medeolariales

This monotypic order is represented by *Medeolaria farlowii*, a pathogen of *Medeola virginiana*, a small tuber-bearing plant found in eastern North America (Thaxter, 1922). Korf (1973), in Eriksson (1982), placed this taxon in its own family and order but with uncertain placement within Ascomycota presumably due to lack of characters (including ascomatal and ascus types) that unite it with other clades. Based on the phylogenetic reconstruction of a nuclear ribosomal DNA dataset, LoBuglio and Pfister (2010) transferred Medeolariales into Leotiomycetes. This enigmatic taxon makes a loosely organized hymenium directly below the leaf whorls of its host. The fungus is present in multiple parts of infected plants, including in seemingly uninfected leaves (Pfister and LoBuglio, 2013). *Medeolaria farlowii* has an inamyloid ascus apex and a thus far unknown method of ascospore release from the ascus (Korf, 1973; LoBuglio and Pfister, 2010). Its occurrence is reported as widespread in the northeastern US (Pfister, 1984; Pfister and LoBuglio, 2013).

Micraspidales

The genus *Micraspis* was described by Darker (1963) to accommodate a fungus that caused a foliar disease resembling *Phacidium* snow-blight of *Picea mariana* in Canada. Ascomata (apothecia) and conidiomata are macroscopically indistinct; they are immersed and become erumpent from the host tissue. The genus was historically placed in either Helotiales (Eriksson, 1999; Lumbsch and Huhndorf, 2009) or Phacidiales (Darker, 1963; Korf, 1973; Baral, 2016). However, based on the combination of unique morphological features and a multilocus phylogenetic reconstruction, Quijada et al. (2020) proposed a new family (Micraspidaceae) and order (Micraspidales). Synapomorphic morphological characteristics of *Micraspis* are: the ectal excipulum and covering layers of both ascomata and conidiomata are composed of *textura epidermoidea*, ectal excipulum is covered on the outside by a thick refractive yellowish gel, ascospores germinate at the poles, and conidia are produced directly from germ tubes or ascospore walls (Quijada et al., 2020).

Phacidiales

Quijada et al. (2018) referred to Phacidiales as “a good example of the chaotic situation within the class.” Since Bessey (1907) described the order, different genera and families have been placed in it. Baral (2016) and Quijada et al. (2018) considered four major lineages: Helicogoniaceae, Phacidiaceae, Tympanidaceae, the *Mniaecia* lineage, and *Coma* as Phacidiales *incertae sedis*. However, the 5–15 locus phylogenetic analysis of Johnston et al. (2019) retrieved the *Mniaecia* lineage (as family Mniaceaceae) and Tympanidaceae as highly supported clades within Leotiales. Phacidiales includes both saprobic and parasitic species of plants, fungi, and lichens. Whereas intrahymenial parasitic *Helicogonium* species only form ascogenous hyphae (no ascomata), other members of Phacidiales produce apothecia that open in the prothymenial to mesohymenial phase (fide Kimbrough, 1981b), with paraphyses lacking vacuolar bodies, asci with or without amyloid ring, and ascospores with variable lipid content (Baral, 2016).

Rhytismatales

Fungi in Rhytismatales are plant-associated either as pathogens, endophytes, or saprotrophs with a near-global distribution. Fruiting bodies vary from the earth-tongue to club-shaped members of Cudoniaceae to the host-immersed fruiting structures of Rhytismataceae (the largest family in the order), which may or may not include a stromatic layer that splits open to reveal the hymenium at maturity. Some recognize Cudoniaceae as included within Rhytismataceae (Lantz *et al.*, 2011) while others maintain both families. In the 5–15 locus phylogenetic reconstruction of Johnston *et al.* (2019), Cudoniaceae was retrieved as a well-supported clade within a paraphyletic Rhytismataceae. Although no synapomorphy exists for the modern concept of Rhytismatales, filiform ascospores with a gelatinous sheath are characters present in many taxa. Many genera formerly included in Rhytismatales such as *Propolis*, *Marthamyces*, *Pseudophacidium*, and *Ascodichaena* were recognized as belonging to different clades (Lantz *et al.*, 2011) and subsequently reclassified into other orders (Johnston *et al.*, 2019; Karakehian *et al.*, 2019).

Thelebolales

Historically, most coprophilic discomycetes were placed in Pezizales (Pezizomycetes), however as now conceived that order is composed mainly of taxa with operculate asci. Based on morphology and more recently molecular phylogenetic studies, *Thelebolus* and other allied coprophilic taxa with inoperculate asci were recognized as an independent lineage from Pezizales (Kimbrough and Korf, 1967; Landvik *et al.*, 1998). Species of *Thelebolus* have cleistothecoid ascomata with variable numbers of ascospores per ascus, ranging from 8 to more than 1000 spores (Kimbrough, 1981a). An expansive definition of the order now includes Pseudeurotiaceae in addition to Thelebolaceae (Johnston *et al.*, 2019; Batista *et al.*, 2020). Coprophilic and psychrophilic species are found in both of these families (Robinson, 2001; de Hoog *et al.*, 2005) although morphologically they differ significantly, hence their previously unrecognized relationship (Baral, 2016). Species of Pseudeurotiaceae form immersed or superficial cleistothecia on wood and decaying plant material. *Pseudogymnoascus destructans*, the causal agent of white-nose syndrome in bats, is a member of this family but only known from its asexual state. Little work has been done to understand the systematics of the family Pseudeurotiaceae (Minnis and Lindner, 2013).

Biases in Sampling of Leotiomycetes

Distributional Unevenness

Geographically, Leotiomycetes are found on all continents including Antarctica, but their taxonomy has been based primarily on the diversity in the temperate Northern Hemisphere, especially in western Europe and the United States, while tropical locations are underrepresented (Fig. 3; Piepenbring *et al.*, 2018). Leotiomycetes and Helotiales in particular include some of the oldest descriptions of mycological taxa (Micheli, 1729). As the cradle for fungal taxonomy, Europe has been well-documented in terms of Leotiomycetes diversity, with early workers such as Pier Antonio Micheli (Italy, 1679–1737), Marie-Anne Libert (Belgium, 1782–1865), Elias Fries (Sweden, 1794–1878), Heinrich Rehm (Germany, 1828–1916), Émile Boudier (France, 1828–1920), and Pier Andrea Saccardo (Italy, 1845–1920). Of the 630 genera that have been placed in the class, 85% are based on species described from temperate Europe and to a lesser extent North America, whereas only 5% are based on species described from the tropics, Asia, or the temperate Southern Hemisphere, with the fewest descriptions from Africa (Haelewaters *et al.*, 2021).

Recent efforts in North America have focused mostly on macrofungi (Bruns, 2011; 2012) but there are some reports of undescribed and rare Leotiomycetes – including taxa that were previously unsequenced. Localities include New Brunswick, Canada (Quijada *et al.*, 2020), the Rocky Mountains in Colorado (C.A. Quandt, unpublished), Boston Harbor Islands National Recreation Area in Massachusetts (Haelewaters *et al.*, 2018a), and Great Smoky Mountains National Park in North Carolina and Tennessee (Hustad and Miller, 2011).

Helotiales, a Mega-Order in Disarray

Since the description of Helotiaceae (Rehm, 1896), this family has been expanded with 100s of species such that it currently is the most speciose family of the order Helotiales. Several taxa within the family, such as *Hymenoscyphus*, turned out to be polyphyletic (Stenroos *et al.*, 2010; Baral *et al.*, 2013; Baral *et al.*, 2015; Johnston *et al.*, 2019). Also higher taxa within Helotiales have been shown to be polyphyletic, although phylogenetic results from different studies heavily depend on taxon sampling and the number of loci used to estimate evolutionary relationships. Baral *et al.* (2015) found that Helotiaceae and Lachnaceae were paraphyletic based on the phylogenetic reconstruction of an ITS–LSU dataset. Johnston *et al.* (2019), on the other hand, presented a 5–15 locus tree in which both Helotiaceae and Lachnaceae were monophyletic. Taxon sampling within Helotiaceae differed between the two studies but mostly overlapped for Lachnaceae, clearly showing the importance of multiple, phylogenetically informative loci.

Baral *et al.* (2015) referred to several helotialean families and subfamilies as wastebaskets. Throughout the years, several taxa were described in these higher lineages based on morphological synapomorphies – traditionally, the morphology of ascomata (Zhang and Wang, 2015). As an example, the subfamily Encoelioidae encompassed taxa with long-lived and desiccation-tolerant apothecia. However, a five-locus phylogenetic analysis revealed that Encoelioidae was highly polyphyletic (Pärtel *et al.*, 2017).

Fig. 3 Global distribution of Leotiomycetes collections deposited in database herbaria, based on a dataset of 217,480 records downloaded from MyCoPortal (2020). Insets show closer views of collections from the continental US and Europe.

Species known or combined as *Encoelia* were retrieved in seven different genera in six families, two of which had to be resurrected (Cenangiaceae and Cordieritidaceae). As more multi-locus sequences and genome-scale data become available, researchers are learning that several of the characters once thought to define a higher taxon have multiple origins in the order.

Evidently, several taxa once considered as Helotiales are now recognized as members of new, distinct orders. In addition, in recent years and often based on molecular phylogenetic studies, several new families have been erected within the order and several more unnamed lineages proposed (Han *et al.*, 2014; Baral, 2016; Crous *et al.*, 2017; 2018; Pärtel *et al.*, 2017; Baral and Polhorský 2019; Johnston and Baschien, 2020). Johnston *et al.* (2019), supported by their 5–15 locus and genome-scale phylogenies, chose to recognize a larger, more inclusive definition of Helotiales in lieu of a more restricted definition, which would have necessitated the creation of several new orders. The highly diverse mega-clade Helotiales sensu Johnston *et al.* (2019) also includes the previously segregated order, Erysiphales, the powdery mildews, which encompasses more than 976 species in 20 genera (Marmolejo *et al.*, 2018; Wijayawardene *et al.*, 2020). However, not all authors agree with this proposal because of the morphological and ecological distinctiveness of powdery mildews (Ekanayaka *et al.*, 2019; A.H. Ekanayaka and K.D. Hyde in Wijayawardene *et al.*, 2020).

Understudied Ecological Niches

Historically, the majority of Leotiomycetes have been described from decaying, terrestrial plant materials. However, based on environmental studies, we know that Leotiomycetes, such as the psychrophilic *Pseudogymnoascus* (Rosa *et al.*, 2019) and the mycorrhizal symbiont of moss, *Rhizoscyphus*, are dominant members of polar environments (de Hoog *et al.*, 2005; Bridge and Spooner, 2012; Rosa *et al.*, 2019). Culture-based studies have isolated Leotiomycetes from marine (Baral and Rämä 2015; Fryar *et al.*, 2019) and a multitude of freshwater aquatic environments (Baschien *et al.*, 2013; Tsui *et al.*, 2016). The so-called Dark Septate Endophytes, most of which are Leotiomycetes, can be dominant in Alpine ecosystems. Studies based purely on DNA barcoding have suggested that Leotiomycetes are dominant in many environments including peat bogs (Lamit *et al.*, 2017), the

arctic tundra, and in tropical montane soils (Tedersoo *et al.*, 2014). These studies, however, are often limited in their geographical scope and many of the detected taxa have no names.

Future Research Perspectives

Much has changed in the field of evolutionary biology since Leotiomycetes has been tackled holistically, in addition to the widespread availability and low cost of whole-genome sequencing. Improved technologies and techniques including amplicon-based sequencing, single-cell genomics, metagenomics, transcriptomics, and high-throughput computing, have the ability to transform our understanding of the diversity and ecology in this class. Examples of both culture-dependent studies and environmental sequencing work suggest that Leotiomycetes diversity is broader than currently understood. It is estimated that only 5–7% of Leotiomycetes diversity has been formally described. This warrants a focus on taxa that are difficult to culture and undersampled geographic areas and habitats that could be diverse in Leotiomycetes. Examples of such areas are tropical and subtropical regions around the world, Africa, and much of the Asian continent. Efforts are being undertaken to fill some of these distributional gaps of leotiomycetous knowledge, with fieldwork planned in southeastern Africa (Mozambique) and northern Asia (Siberia). In addition to targeted sampling of geographic areas, certain taxonomic lineages that are currently lacking molecular phylogenetic studies should be targeted in future research. Taxonomically poorly sampled regions of the class have recently produced many phylogenetically distinct genus-level and family-level clades (e.g., Somrithipol *et al.*, 2017; Quijada *et al.*, 2018), and others that remain unnamed (Johnston *et al.*, 2019). Other higher taxonomic level groups that need taxonomic revision include Lahmiales and Thelebolales, in addition to groups such as Calloriaceae, Hyaloscyphaceae, and the “*Stamnaria* lineage” in Helotiales and Cudoniaceae + Rhytismataceae in Rhytismatales. Finally, any molecular phylogenetic data for the 170 *incertae sedis* genera throughout the class would greatly contribute to our understanding of evolutionary relationships of Leotiomycetes. It is likely that these sampling initiatives will reveal undescribed clades within the class and thereby help to resolve some of the deeper nodes that have not yet received support.

Introduction

The Pezizomycetes comprise a single order, Pezizales, with ≥ 22 families currently recognized. Along with the Orbiliomycetes, the class represents one of the basal lineages among the filamentous Ascomycota (Shen *et al.*, 2020). The class is thought to have originated between 400 and 540 mya (Beimforde *et al.*, 2014; Martin *et al.*, 2010; Murat *et al.*, 2018). The full diversity of the order has yet to be completely documented since previously undetected lineages continue to be found through application of molecular methods. There are approximately 200 genera and perhaps 2000 species. Ascomata are epigeous (above ground), or hypogeous (below ground). The truffles of commerce belong to this latter group. The epigeous ascomata are apothecial, cleistothecial or are highly reduced. The reduced forms are composed of only a few asci in clusters on vegetative hyphae with little or no sterile supporting tissue (excipulum). In the epigeous lineages, ascospores are generally forcibly released by an opening at the ascus apex resulting in the formation of an operculum, or lid. Hypogeous members occur in several of the families. There are at least 30 independent origins of truffle-like members (Alvarado *et al.*, 2011, 2016; Cabero *et al.*, 2016; Grupe *et al.*, 2019; Hansen *et al.*, 2013; Kraisitdomsook *et al.*, 2019; Kumar *et al.*, 2017; Læssøe and Hansen, 2007; Smith, 2014; Smith and Healy, 2009; Trappe *et al.*, 2010).

Distribution and Ecology

Pezizomycetes can be found around the world but representatives are unevenly distributed. Members of certain families, especially those found in or on soil, show a particularly high diversity in temperate regions (Tedersoo *et al.*, 2014). These include the Pezizaceae, Morchellaceae, Helvellaceae, Rhizinaceae and many of the Pyronemataceae. Others are more abundant in tropical or subtropical regions, as exemplified by the Sarcosomataceae, Wynneaceae and Sarcoscyphaceae. Members of bryophilous Pyronemataceae are particularly common and diverse in the Arctic and Antarctic, but these fungi also occur in other regions (Olech and Mleczko, 2000; Schumacher, 1993). Although fieldwork and discovery in the Pezizomycetes is robust, recent work has shown that even in localities considered well studied, such as the Northern Hemisphere, new species have come to light. In the Southern Hemisphere, much remains to be documented.

Nutritionally Pezizomycetes are saprobic, mutualistic as mycorrhizae (Tedersoo *et al.*, 2006) or as endophytes (Arnold, 2007), or parasitic on bryophytes or vascular plants (Hansen and Pfister, 2006). An additional nutritional niche was recently discovered where some species were documented as bacterial farmers (Pion *et al.*, 2013), or otherwise mutualistic with certain bacteria (Benucci and Bonito, 2016; Giordano *et al.*, 2013; Splivallo *et al.*, 2015).

The plant parasitic species are scattered in various lineages. *Rhizina undulata* is reported as a root parasite of conifers (Ginns, 1968). *Pithya* species may cause branch dieback in conifers. *Caloscypha fulgens* is reported as a seed pathogen of conifers (Paden, 1972; Salt, 1974; Sutherland and Woods, 1978; Paden *et al.*, 1978). *Urnula craterium* has been implicated as the causal agent of strumella canker in oak (Davidson, 1950). *Phymatotrichopsis omivivora* is a serious root pathogen of cotton and other dicotyledonous plants and is known only in its asexual state (Uppalapati *et al.*, 2010). Several Pyronemataceae are parasitic on bryophytes, including species of *Filicupula*, *Lamprospora*, *Moravecia*, *Neottiella*, *Octospora*, *Octosporella*, and *Octosporopsis* (Döbbeler, 1979; Egertová and Sochor, 2017; Hansen and Pfister, 2006; Sochorová *et al.*, 2019; Stenroos *et al.*, 2010). Apothecia occur directly on their moss or liverwort hosts or on surrounding soil. These often parasitize the rhizoids (Döbbeler, 1979; Stenroos *et al.*, 2010). There is evidence that species of *Wynnea* are parasitic on mushroom species in the genus *Armillaria* (Xu *et al.*, 2019).

With the advent of molecular approaches to studying fungal ecology, such as the sequencing of ectomycorrhizal root tips, a number of examples of mycorrhizal Pezizomycetes have been documented. Mycorrhizal Pezizomycetes most commonly form ectomycorrhizae with a broad range of angiosperm and coniferous tree species in boreal, temperate, and Mediterranean forests in the Northern Hemisphere and temperate forests of the Southern Hemisphere (Tedersoo and Smith, 2013; Tedersoo *et al.*, 2010), and with Cistaceae and some Rosaceae in arid shrub lands and deserts (Giovannetti and Fontana, 1982; McDonald *et al.*, 2010), but a few are also tropical (Tedersoo and Nara, 2010). Tedersoo and Smith (2013) hypothesized 20 independent origins of the ectomycorrhizal symbiosis in the Pezizomycetes although evidence is still equivocal for some lineages, such as *Sowerbyella*. *Sphaerospora* species are ectomycorrhizal, but unusual in that they can grow saprobically as well (Danielson, 1984; Sánchez *et al.*, 2014). Some species of Tuberaceae and Pyronemataceae form orchid mycorrhizae with certain understory terrestrial orchids (Bidartondo and Read, 2008; Těšitelová *et al.*, 2012). Morphologically Pezizomycete ectomycorrhizae have a thin mantle, a well-developed Hartig net and they generally form short-distance or contact-type mycorrhizas without rhizomorphs (Agerer, 2001; Tedersoo *et al.*, 2006; Wei *et al.*, 2010). Most of the mycorrhizal Pezizomycetes fruit in or on soil, particularly in disturbed areas or in soil with a neutral or elevated pH (Tedersoo *et al.*, 2014) and low content of organic matter. Petersen (1985) provides a review of the edaphic factors involved in growth and reproduction.

Truffle or truffle-like taxa are largely found within ectomycorrhizal lineages. However, truffles in the Tarzettaceae, Glaziellaceae, and some in the Pezizaceae such as *Carbomyces*, *Kalaharituber* and *Eremiomyces* are not known to be mycorrhizal. Their nutritional strategy is presumed to be saprobic (Hansen *et al.*, 2013; Kumar *et al.*, 2017). In some families, such as Chorioactidaceae, Sarcoscyphaceae and Sarcosomataceae, there are no truffle-like species and no mycorrhizal species are known.

Some non-ectomycorrhizal lineages of Pezizomycetes have been detected as a relatively small component of the endophytic community in healthy leaves, bark, branches and/or roots (Arnold, 2007). Lineages of endophytic Pezizomycetes include non-mycorrhizal Pezizaceae (Arnold, 2007), Sarcosomataceae (Wang *et al.*, 2005), Pyronemataceae and Tarzettaceae (Tedersoo *et al.*, 2013). *Sphaerosporella* species (in a complex of species under the name *S. brunnea*) are an exception to this observation as they have been reported as both endophytic and ectendo- or ectomycorrhizal with a broad range of hosts. However, endophytic and mycorrhizal *Sphaerosporella* are not usually detected on the same tree (Hughes *et al.*, 2020). Detected endophytic Pyronemataceae were mostly pyrophilous species (Raudabaugh *et al.*, 2020; Tedersoo *et al.*, 2013). Many lineages have also been found within lichen thalli (Tedersoo *et al.*, 2013).

The majority of Pezizomycetes are saprobic. They occur on organic material of various types – decaying wood, dung, leaf litter and twigs. The diversity of Pezizomycetes on dung is well documented with many studies and keys available (Bell, 1983; Doveri, 2004; Richardson and Watling, 1968). Some clades, such as the Ascobolaceae, are found almost exclusively on dung (Brummelen, 1967). Dung inhabiting species are also found in several clades of the Pseudombrophilaceae, Pyronemataceae and Pezizaceae (Hansen *et al.*, 2001; Hansen and Pfister, 2006; Perry *et al.*, 2007). In most cases little is specifically known of the biology of saprobic species in regard to nutrient requirements and utilization. Sarcoscyphaceae, Sarcosomataceae and Chorioactidaceae are found exclusively on wood, leaves and plant debris and are presumed to be saprobic.

There are a number of pyrophilous taxa for which fruiting is enhanced by fire or they fruit only after a burn. These are part of a succession of fungi colonizing burned areas, and these species are from various families including Morchellaceae, Pezizaceae, Pyronemataceae, Rhizinaceae, and Tarzettaceae. There is evidence that these fungi may persist in soil, the living tissues of bryophytes ferns, lichens and lycopods, woody debris and other substrates. Fire triggers the release of the fungus (Hughes *et al.*, 2020; Raudabaugh *et al.*, 2020). Certain species of the economically important morels (*Morchella* sp.) are stimulated to fruit prolifically after burns (Alexander *et al.*, 2002; Larson *et al.*, 2016; Pilz *et al.*, 2004).

Morphological Features

Ascomata

Apothecia are the basic type of ascomata in the Pezizomycetes. These range in size from several millimeters to about 20 centimeters and they vary from sessile cups of small to large size to stalked cups to the stipitate-pilae structures found in the Helvellaceae, Discinaceae, and Morchellaceae. Some highly reduced members, such as species of *Ascodesmis*, produce little more than small fascicles of asci. More highly reduced forms are found in *Eleutherascus* and *Monascella* (Guarro and Arx, 1986) in which solitary asci are produced on hyphae or in clusters on unspecialized hyphae. Ascomata are often highly pigmented, particularly the hymenium. Carotenoid pigments have been characterized (Arpin, 1968). Other pigments may give the hymenium brown, orange, purple or black colors.

Variation in typical apothecial ascomata are found, some examples are presented in Fig. 1. On the one hand there are highly reduced types that are merely asci scattered on hyphae as mentioned above but also small cleistothecial (closed) ascomata are found in a few cases. In the case of *Orbicula parietina*, active discharge has been lost and spores are liberated in a powdery mass (Hansen *et al.*, 2005). *Heydenia alpina* forms stalked cleistothecial fruitbodies and is closely related to *O. parietina* (Leuchtmann and Cl  men  on, 2011). It is a small fungus that occurs on plant debris and mosses. It is stipitate with a dark stipe that is topped by a pale mass of hyaline spores and radiating hyphae. No asci are present in mature specimens. Molecular evidence confirms that this species belongs in the Pseudombrophilaceae along with *Orbicula*. The two genera share characteristics of a cleistothecial fruitbody and asci that disintegrate early in the development of the ascomata but they are different in important morphological features (Leuchtmann and Cl  men  on, 2011). These genera were often placed outside of the Pezizomycetes and, in the case of *Orbicula*, confused with Myxomycetes.

Truffle fruitbodies are found in a number of lineages. Following the terminology of Weber *et al.* (1997) these ascomata have been characterized by the position of the asci and the hymenia in relationship to the tissues of the ascomata. Stereothecia are ascomata that lack a hymenium, the asci being scattered individually or in chambers in the mass of sterile tissue. When the hymenium is located on the outside of an ascoma the term exothecium is used. In some cases the hymenium is present as a distinct layer but the ascoma is highly convoluted; this type of ascoma is termed a ptycothecium. All of these specialized types of ascomata are derived from apothecial forms. The literature on many of these taxa as a whole is reviewed in Ekanayaka *et al.* (2018), L  ss  e and Hansen (2007) and O'Donnell *et al.* (1997).

Some highly reduced forms are found among the bryophyte parasites. The ascomata are partly closed and have only a few asci and are reminiscent of perithecia.

The Hymenium

This is the layer composed of asci and paraphyses that line the surface of the apothecium. Asci are the structures in which karyogamy and meiosis occur in the life cycle of the Ascomycota. The asci arise from ascogenous hyphae, which in turn have formed after the process of plasmogamy between two receptive structures from compatible individuals. Ascogenous hyphae are

dikaryotic. These dikaryotic cells may proliferate by the production of croziers. Croziers are hook-like structures formed at the base of the ascus. They are formed by an outgrowth of the ascus before karyogamy and allow for the formation of a new dikaryotic cell. This aids in the proliferation of the dikaryotic system and gives rise to additional asci. Although considered a characteristic of the filamentous Ascomycota, not all Ascomycota produce croziers. Along with asci, the hymenium generally has paraphyses. These are located between the asci and arise from the sterile tissues surrounding the developing ascogenous hyphae.

The Ascus

Brummelen (1994,1978) summarized the structural characters of the ascus in the Pezizomycetes. Important characters are the apical apparatus, the operculum in most taxa, its position, the reaction of the ascus wall layers in various staining agents as seen in light microscopy and the ultrastructure of the ascus walls. Asci that stain blue in iodine-containing reagents (said to be amyloid) are found in Pezizaceae and Ascobolaceae (Hansen *et al.*, 2001) but this character has been lost several times in members of the Pezizaceae, most notably in some of the hypogeous species. Amyloid asci are not found outside these families. The bluing material is a long-chain polysaccharide. The function of this polysaccharide is unknown but it seems to be located on the outer surface of the wall and is sometimes seen in the gelatin matrix of the hymenium (Samuelson, 1978).

The layering of the wall as seen in TEM helps delimit groups, particularly the taxa with thick lateral walls in the Chorioactidaceae, Sarcoscyphaceae and Sarcosomataceae. The asci of these fungi were termed “suboperculate” by Le Gal (1953, 1946) because of their thick, sometimes eccentrically placed operculum. Later Eckblad (1968) and Samuelson (1975) discounted the term finding that the opercula were variously placed and wall construction conformed with that of other Pezizomycetes. In these groups the operculum is often eccentrically positioned at the ascus tip.

Asci are typically cylindrical in shape, and there are usually eight ascospores per ascus. Ascus shape can vary and spore number is often reduced in some truffle-like species, and spores may be more numerous in certain coprophilous species. In most epigeous members ascospores are actively discharged from the ascus by the build-up of osmotic pressure within the ascus. This causes a rupture at thinner areas at the apex of the ascus which creates the operculum. The releasing pressure causes the wall to give way and for the operculum to fold back allowing the ascospores and the cytoplasm of the ascus to be expelled. In some cases the asci deliquesce or are mechanically broken down and dry powdery masses of spores are produced, as in *Orbicula*. In these cases the spores are passively liberated and spread by air currents. Not all members of the Pezizomycetes have opercula or forcible discharge of ascospores. Hypogeous taxa (Læssøe and Hansen, 2007) and some cleistothecial forms (Hansen *et al.*, 2005) have lost the operculum and spores remain either within asci until the fruitbody is eaten or broken down, or the asci disintegrate and a powdery mass is formed. Most hypogeous species produce odors that attract animals and the fruiting bodies are eaten. Ascospore liberation and dispersal for these truffle-like fungi occurs through the process of digestion and excretion.

Ascospores

No member of the Pezizomycetes has septate ascospores. Septa may develop as spores germinate but only at the time a germ tube has been established. The spores may take on a variety of shapes from globose to naviculate. Spore surfaces may be smooth or with various types of surface ornamentations. Generally the ornamentations are derived from deposition of secondary wall material although a few examples of spore ornamentation without a contribution of secondary walls are known. The spore walls are multilayered and the thickness of each wall is highly variable (Merkus, 1976). Most ascospores are hyaline but purple, brown or yellowish ascospores are known. The number of nuclei per spore varies from 1, 2, 4 to many and such variation has been shown to have some taxonomic value (Berthet, 1964; Korf, 1972, 1973). Ascospores also may contain an oil guttule, which is seen under the light microscope as a refractive body within the spore. The number of guttules can also vary; some spores have one guttule, some have two guttules and in some species there are many small guttules in each spore. In some taxa there are no oil droplets. Spore guttulation may provide an important taxonomic character in identification at the genus and species level. It is important to understand that guttulation may be altered when specimens are dried, under such conditions oil droplets may fuse into a single large inclusion.

Paraphyses

Hymenium color is attributed to pigments found in the paraphyses. Yellow, red and orange carotenoid pigments are distinctive features of some of these fungi. These pigments are often present in lipid inclusions in the paraphyses. There are a variety of carotenoid pigments known to occur in these fungi as summarized by Arpin (1968). Other pigments are present either within the cytoplasm of the cells of the paraphyses or encrusted on the cell surface. The chemical composition of these other pigments is largely unknown; they give the hymenium brown, purple or black coloration. Paraphyses are generally septate. The individual cells in the paraphyses may be either uninucleate or multinucleate and this can be useful for classification (Berthet, 1964; Pfister *et al.*, 2008). In some species paraphyses are interspersed with hyaline or darkly pigmented, often thick-walled, elements or setae. Examples of such setae are found in members of the Rhizinaceae, Sarcosomataceae, Chorioactidaceae, and Sarcoscyphaceae. Paraphyses may be simple (unbranched) or they may branch either at the base or along their length. They may also anastomose (fuse) with a cell of a neighboring paraphysis. The apical cell may be the same width as subtending cells or it may be swollen, curved or bent. In some hypogeous species (e.g., *Genea* spp.), paraphyses that have elongated substantially beyond ascus length may interweave to form an epithecium over the asci.

Septal Structures

Ultrastructural characters of septal pore plugs and Woronin bodies correlate to some degree with families and lineages in the class. Kimbrough (1994) summarizes much of the information. Septal pores in vegetative hyphae generally have a lamella embedded in a matrix. Woronin bodies are generally associated with septa. The Woronin bodies take on several morphologies – globular, hexagonal or cylindrical, ranging from globose to considerably elongate. The form of the Woronin bodies is an important taxonomic and phylogenetic character. The septa at the base of the asci also provide important characters. The simplest septal pore structure is the uni- or biconvex band found in the Pezizaceae. Other families exhibit asci with basal septa that are occluded by dome-shaped, pyramidal, or dumbbell-shaped structures. These plugging structures show electron dense bands, or lamellate structures that in some species produce ray-like extensions. In general, Woronin bodies are not found in the asci of Pezizales (but see *Leucangium* in Li, 1997).

Anamorphic States

Anamorphic states have been reported across many families, though they are not known in Glaziellaceae, Helvellaceae, Karstenellaceae, Otideaceae, or Pseudombrophilaceae. Fig. 2 provides some examples of the conidia and modes of conidial formation of members of the class. Conidia are holoblastic (spores are blown out from, and produced with both inner and outer wall of the conidiogenous cell) in development and are hyphomycetous (occurring in cushions or mats). In cases where the mitotic spores germinate to produce hyphae they are considered true conidia (e.g., Paden, 1967; Sánchez *et al.*, 2014). In many cases, however,

Chromelosporium-like state (Pezizaceae) found in *Peziza* species, redrawn from Seifert *et al.* (2011); C. Reduced Ostracoderma-like state (Pezizaceae), redrawn from Berthet (1964); D. Conidial state of *Hydnocystis transitoria* (Tarzettaceae), Kumar *et al.* (2017); E. Conoplea-like state of a *Plectania* species (Sarcosomataceae), redrawn from Ellis (1971); F. Conidial state of *Chorioactis* geaster, redrawn from Peterson *et al.* (2004); G. *Verticicladium*-like state of *Desmazierella acicula* (Chorioactidaceae), redrawn from Ellis (1971); H. *Tuber* species (Tuberaceae), redrawn from unpublished images, R.A. Healy; I. *Ostracoderma* state of *Peziza varia* (Pezizaceae), redrawn from unpublished images, R.A. Healy; J. *Complexipes* species (Pyronemataceae) clamydospore, redrawn from Yang and Korf (1985); K. *Geniculodendron* state of *Caloscypha fulgens* (Caloscyphaceae), redrawn from Paden (1978); L. *Dichobotrys*-like state of *Trichophaea abundans* (Pyronemataceae), redrawn from Carmichael *et al.* (1980); M. *Dichobotrys*-like state of *Pyropyxis rubra* (Pyronemataceae), redrawn from Egger (1984); N. *Mollardiomyces* state of *Nanoscypha tetraspora* (Sarcoscyphaceae) redrawn from Pfister (1973).

germination of mitotic spores has not been observed and this suggests that mitotic spores may act as spermatia and are thus involved in the establishment of the dikaryon. Although sexual reproduction with spermatia in saprobic Pezizomycetes has long been documented, (e.g., Bistis and Raper, 1963; Harper, 1900) it is unverified in Pezizomycetes of other nutritional modes. However, sexual outcrossing is known in *Tuber* (Murat and Martin, 2008) and suggests a possible role of mitospores in plasmogamy. The investigations by Healy *et al.* (2013) identified spore mats in several clades in the Pezizaceae and Tuberaceae that are composed of masses of mitospores. Several anamorphic states with no known teleomorphs within the Pezizomycetes have been discovered through molecular phylogenetic studies. Most notable among these is *Phymatotrichopsis omnivora*, the cotton root pathogen. This falls within the Rhiziniaceae based on molecular studies but despite intensive study of this important pathogen, no evidence of a teleomorph has been discovered (Duggar, 1916; Marek *et al.*, 2009; Uppalapati *et al.*, 2010). Another example is *Cephalophora*, a soil and dung inhabiting fungus, and one that has been implicated in causing keratitis (Goos, 1964; Hoog *et al.*, 2000).

Genomes, Microbiomes, and Model Organisms

A few Pezizomycetes have been used as model organisms. These include species in the genera *Ascobolus* where classic genetic information has been collected (Decaris *et al.*, 1974) and *Pyronema confluens*, which has been used in research on ascocarp development as well as in studies of light detection and circadian rhythms (Traeger *et al.*, 2013; Traeger and Nowrousian, 2015; Nowrousian and Kück, 2006). Comparative fungal genomics has paved the way to a broader and deeper understanding of fungal evolution, phylogenetic structure, sexual reproduction, pathogenicity and epidemiology of plant pathogens, symbiosis and other fungal biology topics (e.g., Gow, 2005; Grigoriev *et al.*, 2014; Howlett *et al.*, 2015). Despite the systematic position of the Pezizomycetes as an early derived lineage of the Pezizomycotina, along with the Orbiliomycetes, there has been relatively limited whole genome sequencing within the class. There are currently 36 complete genomes of Pezizomycetes, out of 775 genomes known for the entire subphylum Pezizomycotina (Shen *et al.*, 2020). Much of the work has focused on edible members of economic importance, such as the morels, desert truffles and “true” truffles of the Morchellaceae, Pezizaceae, and Tuberaceae (Martin *et al.*, 2010; Murat and Martin, 2008; Murat *et al.*, 2018). Analyses of the *Tuber melanosporum* genome unveiled some of the genes involved in mycorrhizal symbiosis (Martin *et al.*, 2010), and revealed the heterothallic nature of this species as well as predicting some of the genes involved in mating (Martin *et al.*, 2010, 2013).

Complete genomes of Pezizomycetes include the following: *Ascobolus immersus*, *Ascodesmis nigricans*, *Caloscypha fulgens*, *Choromyces venosus*, *Geopyxis carbonaria*, *Gyromitra esculenta*, *Kalaharituber pfeilii*, *Leucangium carthusianum*, *Morchella* (9 species), *Peziza echinospora*, *Plectania melastoma*, *Pyronema confluens*, *Rhizina undulata*, *Sarcoscypha coccinea*, *Sphaerosporella brunnea*, *Terfezia boudieri*, *Terfezia clavaryi*, *Tirmania nivea*, *Tricharina praecox*, *Trichophaea hybrida*, *Tuber* (6 species), *Verpa conica*, and *Wilcoxina mikolae*.

The average genome size in the subphylum Pezizomycotina, the filamentous Ascomycota, is around 42 Mb, which is larger than in the other two subphyla of the Ascomycota. The Pezizomycotina have a high number of genes that seem to be derived from prokaryotes whereas this is less common in Saccharomycotina (Shen *et al.*, 2020). The genome sizes of Pezizomycetes can be up to 192 Mb in size, with the genomes of *Tuberaceae* species being significantly larger and more complex than those in other families of Pezizomycetes. For example, genomes of *Morchella importuna* (48 Mb) and *Terfezia boudieri* (63 Mb) are much smaller compared to *Tuber magnatum* (192 Mb). The larger genomes in *Tuberaceae* species are due to the acquisition of an unusually high number of transposable elements (Murat *et al.*, 2018). *Tuberaceae* also has a significantly accelerated evolution of its gene repertoire compared to other ascomycetous species, possibly reflecting an increased rate of genomic evolution underlying traits specific to either symbiosis and/or hypogeous ascomatal formation. The higher rate of evolution has been hypothesized to result from the genome rearrangements caused by repositioning of transposable elements (Martin *et al.*, 2010).

Shen *et al.* (2020) used genomes in reconstruction of an Ascomycota phylogeny. This phylogeny attempted to clarify the relationship of the Pezizomycetes and the Orbiliomycetes in relationship to their position as basal taxa in the Pezizomycotina. Debate had centered on which of these classes were the most basal with several multigene phylogenies showing one or the other to have the most basal position. Shen *et al.* (2020) suggest that the Orbiliomycetes and Pezizomycetes together form a clade that is the sister group to the remainder of the Pezizomycetes.

The microbiome of yeasts, bacteria and fungi that characterize the Pezizomycetes has been an active area of study in recent years. A comparative study of bacterial microbiomes within fruiting bodies and mycelia of four genera of truffles revealed that although there are multiple bacterial genera in the microbiome, one *Bradyrhizobium* genotype was dominant in all analyzed *Tuber* species, regardless of geographic location, but not present to the same degree in the other truffles analyzed (Benucci and Bonito, 2016). *Bradyrhizobiaceae* bacteria have been implicated in the release of sulfur containing compounds from *Tuber borchii* microbiomes. It is thought that a mixture of volatiles produced through interactions among the fungi and bacteria in the microbiome may characterize the odor perceived by humans (Splivallo *et al.*, 2015). These odors help to attract the animals that disperse the spores of truffles, and thus the bacterial-fungal relationship may be symbiotic. Similar studies of other species of epigeous and hypogeous Pezizomycetes may help to understand the extent of such interactions between these fungi and their microbiomes.

Classification and Phylogenetic Studies

The class Pezizomycetes has undergone significant reorganization in recent years due to results from molecular phylogenetic studies. These studies have provided new insights into relationships and have facilitated the evaluation of both morphological and

Fig. 3 Current phylogenetic framework for 22 families of Pezizales. Phylogeny based on maximum likelihood analysis of combined DNA loci (SSU, ITS, LSU, TEF, RPB2). Symbols depict known ascomatal form (epigeous and apothecial or hypogeous and truffle-like) and colors indicate ecological roles in each family. “Mixed” refers to a mixture of trophic modes within a family. Sizes of triangles are approximately proportional to numbers of known species in each family. Graphic of phylogenetic framework modified from Ekanayaka *et al.* with additional families approximately placed as determined by Kraisitudomsook *et al.* and Pfister *et al.* Modified from Ekanayaka, A.H., Hyde, K.D., Jones, E.B.G., Zhao, Q., 2018. Taxonomy and phylogeny of operculate discomycetes: Pezizomycetes. *Fungal Divers.* 90, 161–243. doi:10.1007/s13225-018-0402-z. Kraisitudomsook, N., Healy, R.A., Pfister, D.H., *et al.*, 2019. Resurrecting the genus *Geomorium*: Systematic study of fungi in the genera *Underwoodia* and *Gymnohydnortya* (Pezizales) with the description of three new South American species. *Persoonia* 44, 98–112. doi:10.3767/persoonia.2020.44.04. Pfister, D.H., Quijada, L., LoBuglio, K.F., 2020. *Geodina* (Pezizomycetes: Wynneaceae) has a single widespread species in tropical America. *Fungal Syst. Evol.* 5, 131–138. doi:10.3114/fuse.2020.05.08.

ecological characters. For example, the hypogeous species of Pezizomycetes were almost all previously treated in the order Tuberales due to their convergent morphological forms. However, recent studies have now placed these hypogeous taxa in at least ten different Pezizomycete families. All of these families with hypogeous members have at least some ectomycorrhizal species and indeed nearly all of the hypogeous Pezizomycetes are ectomycorrhizal, with exceptions in Glaziellaceae, Pezizaceae and Tarzettaceae. Fig. 3 shows relationships among the Pezizomycetes as we currently recognize them and also indicates growth habit and trophic status.

The 22 families we currently recognize in the class are summarized below. Apothecial morphology varies greatly, particularly in the larger families; Fig. 1 provides an overview of the patterns of apothecial forms found in this class. Table 1 is a guide to some critical characters of the families.

Families

- (1) *Ascobolaceae* – These generally small apothecial fungi have amyloid asci (asci that give a blue reaction in iodine solutions). This character is shared with the *Pezizaceae* listed below. This reaction is diffuse in the *Ascobolaceae* and is often detected in the gelatinous material in the hymenium. The members of the family are distributed worldwide and are mostly found on dung. A few species are found on soil or burned debris. In *Ascobolus* and *Saccobolus* the spores become purple or brownish at maturity. The genus *Thecotheus*, that occurs on dung but also other substrates, has unpigmented ascospores. Sclerotia are not known in this family. Names used for the anamorphs in *Ascobolus* referred to the form genera *Oidia*, *Papulaspora*, and *Rhizostilbella*. Genera included: *Ascobolus*, *Cleistodophanus*, *Saccobolus*, and *Thecotheus*.
- (2) *Ascodesmidiaceae* – These fungi occur on dung but also on soil and debris. The morphology in the family ranges from a single ascus occurring along hyphae to simple fascicles of a few asci to apothecia with a hymenium and well-developed apothecial tissues. This family is currently placed as the sister group to *Pulvinulaceae* but there is low statistical support for this placement. Sclerotia are not known in this family. The family *Coprotaceae* was recently described recognizing a clade previously detected by Hansen *et al.* (2013). The genera included in this family are *Coprotus* and *Boubowia*. Other genera

Table 1 A guide to salient features of members of the families of the Pezizomycetes. This table is intended to offer guidance for the morphological placement of species within the framework of current families. Note that characters may appear in several columns

Family	Ascus J+	Ascus J−	Ascus + / − thick- walled	Asci indehiscent	Asci opening via an operculum	asci produced in naked fascicles or directly on hyphae	Saprobic	Plant parasitic including mosses	Mycorrhizal	Mycoparasitic	Ascomata epigeous	Ascomata hypogeous	ascomata minute cleistothecial or perithecial	ascomata stipitate	ascomata sessile or substipitate	Ascospores uninucleate	Ascospores multi- nucleate	2-4- nucleate	Ascospores hyaline	ascospores pigmented

remaining in the Ascodesmidaceae may also belong here such as *Dictyocoprotus* and *Pseudobobouvia*. Two genera have no known teleomorphs: *Cephalophora* and *Pulchromyces* (Hennebert, 1973; Tanabe et al., 1999; Thaxter, 1903).

Genera included: *Ascothalium* (?), *Ascodesmis*, *Bobouvia*, *Cephalophora*, *Coprotus*, *Dictyocoprotus*, *Eleutherascus*, *Lasiobolus*, *Ochotrichobolus*, *Pseudobobouvia*, *Pseudocoprotus*, *Pulchromyces* (?) and *Trichobolus*.

- (3) Caloscyphaceae – Two apothecial genera are placed in this family: *Caloscypha* and *Kallistoskypha*. *Caloscypha fulgens* is the only species currently recognized in the genus. It is yellow-orange and often colors blue green when handled. *Kallistoskypha* is also a monotypic genus, with *K. incarnata* as the sole member. Ekanayaka et al. (2018) placed it as the only genus in a separate family, Kallistoskyphaceae. However, this placement was based on only two genes in a five-gene analysis, resulting in its placement on a long branch. A study by Pfister et al. (2013) placed this species in the Caloscyphaceae with strong statistical support. More robust molecular data may better resolve the relationships between *Kallistoskypha* and other Pezizomycetes. The ascomata of *K. incarnata* are cupulate, pinkish and the ascospores are globose and smooth. The species has been collected on soil in the Mediterranean region. Because of its association with *Eucalyptus* Pfister et al. (2013) suggested that it may represent an introduction of an australasian fungus to the Mediterranean region. *Caloscypha fulgens* is found on soil in north temperate regions. Sclerotia are not known in this family. The conidial state of *C. fulgens*, known as *Geniculodendron pyriforme*, has been implicated as a seed pathogen of conifers (Salt, 1974).

Genera included: *Caloscypha*, *Kallistoskypha*.

- (4) Chorioactidaceae – Members of this family are characterized by thick-walled asci with sometimes eccentrically-placed opercula. The apothecia are clothed with brown hairs that are generally encrusted with pigmented granules. The ascospores are ornamented with either pits or ridges. There is a tendency for the asci to mature simultaneously within a single apothecium. Sclerotia are not known in this family. The form genus *Kumanasamuha* was applied to the anamorphs in *Chorioactis* and *Trichaleurina* (Carbone et al., 2013; Nagao et al., 2009), and a *Verticicladium*-like conidial state was described for *Desmazierella acicula* (Gremmen, 1949).

Genera included: *Chorioactis*, *Desmazierella*, *Neuronal*, *Psuedosarcosoma*, *Trichaleurina*, and *Wolfina*.

- (5) Discinaceae – There are both epigeous and hypogeous taxa in the family (Læssøe and Hansen, 2007). The hypogeous *Hydnotrya* is ectomycorrhizal; other taxa are saprobic associated with wood, soil with organic matter, or woody debris. The epigeous members are generally large and either stipitate or sessile. Some are distinctive members of the spring funga. Conidial states have been described by Carris et al. (2015) and Healy et al. (2013) and are similar to the *Costantinella* type observed in the Morchellaceae.

Genera included: *Discina*, *Gyromitra*, and *Hydnotrya*.

- (6) Geomoriaceae – The single genus in this family includes both epigeous and hypogeous species. Ascomata are either modified columnar apothecia or exothecia, and vary widely in size from 1 to 40 mm high. Young ascomata are typically white or pale tan but often change to brown, purple, or black as the hymenium matures. The outer excipulum and stipe are only present in the epigeous taxa. Paraphyses may slightly or greatly exceed the asci in length. The asci lack opercula. They are ectomycorrhizal, found in forests or at forest edges, and known only from the Southern Hemisphere. Conidial states and sclerotia are unknown in this genus.

Genus included: *Geomorium*.

- (7) Glaziellaceae – Large hollow ascomata of this fungus are generally formed under or on the surface of soil and debris on the forest floor in tropical localities. The family has a single genus and *G. aurantiaca* is the recognized species (Gibson et al., 1986; Hansen and Pfister, 2006). Other species described as *Glaziella* have since been determined to belong to an unrelated lineage (Thaxter, 1922). Prior to electron microscopy and phylogenetic studies, *G. aurantiaca* was variously placed among the Endogonaceae (Mucoromycota) and other lineages of the Ascomycota. There has been limited molecular sampling of collections of *G. aurantiaca*, which appears to be restricted to the new world. Other species have been assigned to the genus from Asia but these are molecularly unverified. Transmission electron microscopy revealed single-spored asci that deliquesce with maturity (Gibson et al., 1986), and molecular methods placed it in the Pezizomycetes (Landvik and Eriksson, 1994). The trophic status is not known; there is no convincing evidence that it forms ectomycorrhizae. The single-spored globose asci are scattered in the rind-like flesh of the ascomata. Conidial states are unknown in this genus.

Genus included: *Glaziella*

- (8) Helvellaceae – Ascomata are hypogeous or epigeous, they are ectomycorrhizal. Epigeous members are cupulate, ear-shaped, saddle-shape or sparassoid with or without a stipe. They are generally without carotenoid pigments. The asci are thin walled and the ascospores are smooth or irregularly ornamented. Generally there is a single large guttule and there are four nuclei per spore. *Balsamia* and *Barssia*, hypogeous genera, produce stereothecia or ptychothecia.

Genera included: *Balsamia*, *Barssia*, *Helvella*, *Midotis*, *Pindara*, *Underwoodia*.

- (9) Karstenellaceae – The only species in the genus, *Karstenella vernalis*, produces thin apothecia on a resupinate mycelial mat that grows directly on soil (Hansen et al., 2008) or woodland litter (Harmaja, 1969). It is presumed to be saprobic (Ekanayaka et al., 2018) but the ecology of this species is not well-known. Ascospores are bi- or multiguttulate. The species has been collected in widely disjunct geographical regions of Finland and New Mexico, USA (Hansen et al., 2008). There have been no reports of sclerotia or conidial states in this species.

Genus included: *Karstenella*.

- (10) Morchellaceae – The morels are choice edible fungi and the family also has hypogeous members. The family includes the genus *Morchella* that is characterized by large stalked ascomata that have a convoluted and ridged fertile region. *Verpa* is

similarly constructed but with a continuous hymenial layer whereas *Disciotis* is cupulate, sessile and folded or convoluted. *Morchella*, *Disciotis* and *Verpa* are epigeous but there are several hypogeous genera in the family. These produce exothecial, pychothecial or stereothecial ascomata. One, hypogeous species, *Fischerula subcaulis*, has a residual to well-formed stalk. In the past some studies suggested that the species in this group are ectomycorrhizal but at least some species of *Morchella* grow without any ectomycorrhizal host plants nearby and they can be grown in culture. [Tedesoo and Smith \(2013\)](#) suggested that *Fischerula*, *Imaia*, *Kalapuya* and *Leucangium* are ectomycorrhizal based on morphological studies of ECM roots and based on the isotopic signatures of fruiting bodies but more evidence is needed to test this hypothesis. Sclerotia are formed by at least some *Morchella* species ([Ower, 1982](#); [Volk and Leonard, 1989](#)). *Morchella* species have anamorphic states that were previously placed in the form genus *Costantinella*, and *Disciotis* has a similar anamorph ([Carris et al., 2015](#)). An anamorph was also reported for *Fischerula* ([Healy et al., 2013](#)).

Genera included: *Disciotis*, *Fischerula*, *Imaia*, *Kalapuya*, *Leucangium*, *Morchella*, *Verpa*.

- (11) Otideaceae – The family was formerly used by some authors in a broad sense to include many of the Pyronemataceae. In the restricted sense, this family includes the ectomycorrhizal genus *Otidea* and a few others. At least one hypogeous *Otidea* species is known. Ascomata are apothecial in most species, pychothecial in *O. subterranea*, or cleistothecial in *Warcupia*. In *Monascella* the asci are produced on hyphae in small clusters. The genus *Acervus* is apothecial but in early development the ascomata are closed. Species of *Otidea* form ectomycorrhizal associations whereas the other species are presumed saprotrophic. There are no sclerotia or anamorphs reported for this family.

Genera included: *Acervus*, *Arpinia* (?), *Ascosparsis*, *Monascella*, *Otidea*, *Warcupia*, and *Wenylingia*.

- (12) Pezizaceae – Members are ectomycorrhizal or saprobic. Some species occur after fire. They range in size from small to large and generally are fragile due to the large cells that often compose the excipulum. Hypogeous species may be pychothecial, stereothecial, or exothecial. Most members of the family have iodine positive asci (amyloid) but this character is lost in most of the hypogeous taxa and absent in some of the early derived lineages. This family and the Ascobolaceae are the only families with the iodine positive reaction of the asci. The extent, location and strength of the iodine reaction is diagnostic at the clade level. In some species there is a strong wall reaction with or without an apical ring. In other species the reaction is diffuse and often appears to be in the gel surrounding the asci. These differences in reactions in iodine have been discussed by [VanVooren \(2020\)](#), who also established or reinstated several genera to recognize groups within the heterogeneous genus *Peziza*. There are several species-rich hypogeous lineages that are derived within ectomycorrhizal clades (with exceptions noted in previous sections). The desert truffles belong to this family ([Kovács and Trappe, 2014](#)). Among the desert truffles, *Terfezia* and *Tirmania*, are economically important, and in some cases, medically important in the Middle East ([Hamza et al., 2016](#); [Shavit, 2014](#); [Shavit and Shavit, 2014](#)). Sclerotia are produced by species of *Cheilymenia* ([Smith et al., 2015](#)) and *Mattirolomyces* ([Kovács et al., 2007](#)). Anamorphic states described in this lineage were historically placed under the names *Chromelosporium*, *Glischroderma*, *Oedocephalum*, *Ostracoderma*, and *Rhinotrachium* ([Hennebert, 1973](#); [Norman and Egger, 1999](#); [Paden, 1972](#)), and a different anamorphic state was reported for *Hydnobolites* ([Healy et al., 2013](#)). Some of the ectomycorrhizal taxa are only known from their anamorphic states.

Genera included: *Adelphella*, *Ahmadea*, *Amylascus*, *Antrelloides*, *Aquapeziza*, *Babosia*, *Boudiera*, *Calongea*, *Carbomyces*, *Cazia*, *Chromelosporiopsis*, *Cleistoiophanus*, *Daleomyces*, *Delastria*, *Elaiopezia*, *Elderia*, *Eremiomyces*, *Geoscypha*, *Hansenopezia*, *Hapsidomyces*, *Hydnobolites*, *Hydnoplicata*, *Hydnotryopsis*, *Iodophanus*, *Iodowynnea*, *Ionopezia*, *Kalaharituber*, *Legaliana*, *Lepidotia*, *Luteoamyascus*, *Malvipezia*, *Marcelleina*, *Mattirolomyces*, *Mycoclelandia*, *Pachyella*, *Pachyphlodes*, *Paragalactinia*, *Peziza*, *Phaeopezia*, *Phylloscypha*, *Planomyces*, *Plicaria*, *Plicariella*, *Purpureodiscus*, *Rhodopeziza*, *Ruhlandiella*, *Sarcopeziza*, *Sarcosphaera*, *Sphaerosoma*, *Sphaerozone*, *Stouffera*, *Temperantia*, *Terfezia*, *Tirmania*, *Ulurua*.

- (13) Pseudombrophilaceae – Included here are several taxa that are saprobic on dung or decaying plant material. Several of the included taxa, such as *Heydenia* species, *Lasiobolidium orbicularis* and *Orbicula* species, produce cleistothecoid ascomata whereas *Pseudombrophila* species produce apothecia. Sclerotia are formed by some species of *Pseudombrophila* ([Pfister, 1984](#)). Anamorphs are not known in this family.

Genera included: *Heydenia*, *Orbicula*, *Pseudombrophila*, *Lasiobolidium sensu lato*

- (14) Pulvinulaceae – These fungi produce small, pulvinate apothecia on soil. Many are orange or yellow due to carotenoid pigments. Some species in this group produce paraphyses that are clavate to circinate, which is an important diagnostic feature. Species of *Pulvinula* are ectomycorrhizal whereas taxa in the other genera are saprobic. Anamorphs and sclerotia are not known in this family.

Genera included: *Lazuardia*, *Pseudoboubovia*, *Pulvinula*

- (15) Pyronemataceae – Despite a good deal of recent phylogenetic work this family remains difficult to characterize. Some species are saprobic on plant material and dung, others are ectomycorrhizal, and some are endophytic or endolichenic. Several species fruit prolifically in response to fire. Species of several genera are parasitic on bryophytes. Pigmentation ranges from those that are brightly colored with carotenoids to drably colored species lacking these pigments. Although some ascomata are smooth, many members have hairs at the base or hairs or setae that emanate from the excipulum. The family also has some hypogeous and perithecioid species. Sclerotia are produced by some species of *Cheilymenia* ([Smith et al. 2015](#)) and *Pyronema* ([Moore, 1962](#)). Anamorphs have been reported for some lineages, under the form genera names *Actinospora*, *Ascorhizoctonia* (recently separated from *Tricharina* as a holomorphic genus by [Van Vooren et al. \(2017\)](#)), *Complexipes*, *Dichobotrys* and *Micronematobotrys* ([Egger, 1984](#); [Hennebert, 1973](#); [Sun and Guo, 2010](#); [Yang and Korf, 1985](#)). An anamorph was recently described for *Octospora* ([Sochorová et al., 2019](#)). One form genus, *Sphaerosporium*, has no known teleomorph ([Song et al., 2019](#)).

Genera included: *Aleuria*, *Aleurina*, *Anthracobia*, *Ascorhizoctonia*, *Aurantiolechnea*, *Barlaea*, *Boudierella*, *Byssonectria*, *Chaetothersia*, *Chalazion*, *Cheilymenia*, *Cleistothelobolus*, *Cupulina*, *Eoaleurina*, *Filicupula*, *Galeoscypha*, *Genabea*, *Genea*, *Geopora*, *Gilkeya*, *Hiemsia*, *Hoffmannoscypha*, *Humaria*, *Hypotarsetta*, *Jafnea*, *Lamprospora*, *Lasiobolidium sensu stricto*, *Lasiocupulina*, *Lathraeodiscus*, *Leucoscypha*, *Lotinia*, *Luciotrichus* (?), *Melastiza*, *Miladina*, *Moravecia*, *Mycogalopsis*, *Myrmecocystis*, *Neottiella*, *Octospora*, *Octosporella*, *Octosporopsis*, *Oviascoma*, *Parascutellinia*, *Paratracharina*, *Paratrachophaea*, *Parawilcoxina*, *Perilachnea*, *Petchiomyces*, *Picoa*, *Pseudaleuria*, *Pseudotracharina*, *Pyronema*, *Pyropyxis*, *Ramsbottomia*, *Rhizoblepharia*, *Rhodoscypha*, *Rhodotarsetta*, *Scutellinia*, *Sepultaria*, *Sepultariella*, *Smaradaea*, *Smarodisia*, *Sowerbyella*, *Sphaerosoma*, *Sphaerosporium*, *Sphaerosporella*, *Spooneromyces*, *Terracavicola*, *Tracharina*, *Tricharinopsis*, *Trichophaea*, *Trichophaeopsis*, *Wilcoxina*

- (16) Rhizinaceae – Three genera are placed in this family. Species of *Rhizina* and *Psilopezia* are known only as teleomorphs; they occur on wood and woody roots. *Rhizina*, which occurs on burned areas, has been implicated as causing a root rot. *Psilopezia* species grow on wet, water-soaked wood. Spores are large and in *Rhizina* ascospores are smooth and have a pronounced apiculus. Ascogonia in these two genera expand through indeterminate marginal growth. The third genus in this family, *Phymatotrichopsis omnivora*, is a serious pathogen of cotton and other dicots (Marek *et al.*, 2009; Uppalapati *et al.*, 2010). Sclerotia are formed by *P. omnivorum*, and this taxon is only known from its anamorphic state (Marek *et al.* 2009).

Genera included: *Phymatotrichopsis*, *Psilopezia*, *Rhizina*

- (17) Sarcoscyphaceae – These include some of the most charismatic members of the class with their sometimes large apothecia that can be bright red to pink and are sometimes fringed with hairs. Some have a prominent stalk. Asci are thick-walled and the operculum is generally eccentrically placed. The bright colors originate in the paraphyses of the hymenia and the spores tend to be laterally asymmetrical. Spores may be smooth or in some species ornamented with ridges and folds. The ornamentation is cyanophobic (they do not take up cotton blue stain). Some species are found in temperate regions but many others are tropical or subtropical. They are assumed to be saprobes or weak plant parasites. The form genus *Molliardiomyces* has been applied to conidial states in species of *Nanoscypha*, *Pithya*, *Phillipsia* and *Sarcoscypha* (Paden, 1984; Pfister, 1973), and an anamorph has also been described for *Cookeina* species (Boedijn, 1929, 1932).

Genera included: *Cookeina* (including *Boedijnopeziza*), *Komposcypha*, *Microstoma*, *Nanoscypha*, *Phillipsia* (including *Aurophora*), *Pithya*, *Pseudopithyella*, *Rickiella*, *Sarcoscypha*, *Thindia*

- (18) Sarcosomataceae – These fungi are black or darkly pigmented. Like the Sarcoscyphaceae the ascus walls tend to be thick and the operculum is eccentrically placed. The outer layers of the excipulum tend to be encrusted with dark pigments. Spores are thick-walled with or without folds and ornamentation. Often hymenial hairs or setae are present. Species are considered to be saprobic or weakly parasitic on plants. Anamorph states include *Conoplea* and possibly *Strumella* for *Urmula* and *Plectania* (Paden, 1972). At least one species of *Sarcosoma* also produces an anamorph (Paden, 1972).

Genera included: *Donadinia*, *Galiella*, *Korfiella*, *Plectania*, *Pseudoplectania*, *Sarcosoma*, *Selenaspora*, *Urmula*.

- (19) Strobiloscyphaceae – A single genus, *Strobiloscypha*, with two species makes up the family. The species are small, have brown apothecia with olive-toned hymenia, and are presumed to be saprobic, occurring on the dead branches and cones of Cupressaceae (Perić *et al.*, 2013). Even with molecular data, the relationship between Strobiloscyphaceae and other Pezizomycetes is unsettled. Previous placement was speculative, and there is no strong support for its relationships in the most recent treatment (Ekanayaka *et al.*, 2018). A *Verticicladium*-like conidial state was described for one species in this family (Perić *et al.*, 2013).

Genus included: *Strobiloscypha*

- (20) Tarzettaceae – This family contains both epigeous and hypogeous members. Kumar *et al.* (2017) treated the hypogeous members. Wang *et al.* (2016) treated the genus *Geopyxis*. *Tarsetta* is ectomycorrhizal but the nutritional strategies of the other genera are non-mycorrhizal and not well understood. At least some species of *Geopyxis* can act as root biotrophs but there is no strong evidence for ectomycorrhizal formation (Vrålstad *et al.*, 1998). Anamorphs are known for three of the five genera and are similar within the family. The form genera *Dicyma*, *Hansfordia* and *Nodulisporium* have been misapplied to some of these conidial states (Conway, 1975; Egger, 1984; Hennebert, 1973; Paden, 1972; Vrålstad *et al.*, 1998).

Genera included: *Densocarpa*, *Geopyxis*, *Hydnocystis*, *Paurocotylis*, *Tarsetta*

- (21) Tuberaceae – Most species are hypogeous with the exception of two in the Southern Hemisphere genus *Nothojafnea*, which form apothecial ascogonia. All other known taxa form pythothecial or stereothecial ascogonia. All known species are ectomycorrhizal and most are considered early successional. The highly prized “true truffles” in the genus *Tuber* belong to this family. Sclerotia are not reported in this family. Conidial states that are similar in morphology have been described for some species in the *maculatum* and *puberulum* lineages of *Tuber* (Grupe *et al.*, 2018; Healy *et al.*, 2013; Urban *et al.*, 2004).

Genera included: *Choiromyces*, *Dingleya*, *Labyrinthomyces*, *Loculotuber*, *Nothojafnea*, *Reddellomyces*, *Tuber*

- (22) Wynneaceae – Recently separated from the Sarcoscyphaceae based on molecular and ecological data (Pfister *et al.*, 2020). The elaborate fruitbodies of *Wynnea* species arise from a mass of tissues that include hyphae and rhizomorphs of *Armillaria* species. It is suggested that *Wynnea* species may parasitize fungi from the genus *Armillaria* and produce large sclerotia-like bodies built-up of hyphae from both *Armillaria* and *Wynnea* (Xu *et al.*, 2019). The biotrophic status of *Geodina* is unknown but the unusual report of this as occurring on soil suggests that, like *Wynnea* species, it may be associated with another fungus. Anamorphs are not known in this family.

Genera included: *Wynnea*, *Geodina*.

Genera of uncertain position include: *Aparaphysaria*, *Ascocalathium*, *Microeurotium*.

Acknowledgments

We are grateful to Matthew E. Smith for his insightful reading, comments and improvements to the manuscript. Images of ascomata were provided by Matthew Smith (*Geomorium*), Mark Elliot (*Wynnea*), Roy Kristiansen (*Desmazierella*), Arthur Grupe (*Caloscypha*) and Alan Franck (*Glaziella*). Many individuals have contributed through world-wide collecting efforts.

Outline of Basidiomycota

Mao-Qiang He and Rui-Lin Zhao, State Key Laboratory of Mycology, Institute of Microbiology, Chinese Academy of Sciences, Beijing, People's Republic of China

Brief Introduction of Basidiomycota

Basidiomycota R.T. Moore 1980 is a major lineage of fungi embracing more than 40,000 species which takes nearly 1/3 fungal species (Hawksworth and Lücking, 2017; He *et al.*, 2019). It comprises most of the macrofungi including edible and medicinal mushrooms which is a significant part of human diet. It was estimated that the global mushroom market is at US\$36,825.4 million by the end of 2016 and is expected to exhibit a compound annual growth rate (CAGR) of 8.2% from 2016 to 2024, rising to a valuation of US\$69,267.9 million by 2024 (Transparency Market Research, 2016). The top three mushrooms in the market are *Agaricus bisporus* (J.E. Lange) Imbach (button mushroom), *Lentinus edodes* (Berk.) Singer (Shiitake Mushroom) and *Pleurotus ostreatus* (Jacq.) P. Kumm. (Oyster Mushroom). Medicinal mushrooms have an established history of use in traditional ancient therapies. They contain biologically active polysaccharides in the basidiomes which were associated in many medicinal studies of antitumor, immunomodulating, antioxidant, radical scavenging, cardiovascular, antihypercholesterolemia, antiviral, antibacterial, antiparasitic, antifungal, detoxication, hepatoprotective, and antidiabetic effects (Gao *et al.*, 2002, 2003, 2004; Wasser and Didukh, 2003; Rowan *et al.*, 2003; Zhang *et al.*, 2007; Dai *et al.*, 2009). Some famous species are Ling Zhi (*Ganoderma lingzhi* Sheng H. Wu, Y. Cao & Y.C. Dai), Sanghuang (*Sanghuangporus* Sheng H. Wu, L.W. Zhou & Y.C. Dai), *Inonotus obliquus* (Pers.: Fr.) Pilát, and *Fomitopsis officinalis* (Vill.: Fr.) Bond. et Singer (Poder, 2005; Cao *et al.*, 2012; Zhou *et al.*, 2016). Meanwhile, many poisonous mushrooms are also well-known due to its lethality, for example, death cap (*Amanita phalloides* (Vail. ex Fr.) Link), which killed thousands of people throughout the history, was on the world's ten most feared fungi list (Hyde *et al.*, 2018). Besides the macrofungi, plant pathogenetic smut, rust and industrial important yeast are also members of Basidiomycota. Rust fungi as a group are among the most economically important pathogens of many native and cultivated plants, for example, wheat steam rust (*Puccinia graminis* Per.) and coffee leaf rust (*Hemileia vastatrix* Berk. & Broome). Diseases caused by rust fungi are the major concerns and sometimes limiting factors for successful cultivation of such internationally important crops as wheat, corn, coffee and pine (Cummins and Hiratsuka, 2003).

In the ecosystem, species of Basidiomycota are possibly the main contributors to wood and litter degradation, including degradation of the different components of wood, and they play a key process in carbon recycling (Pelaez *et al.*, 1995; Pointing, 2001; Pointing *et al.*, 2005; Oberwinkler, 2012). They form symbiotic relationships with plant species called ectomycorrhizal which play a fundamental role in the nutrient cycle in terrestrial ecosystems, especially in forest systems (Domínguez-Núñez and Albanesi, 2019). They also form symbiotic relationships with insect, for example, species of *Termitomyces* R. Heim, which grow as symbionts in the termite nests. The basidiomes cultivated by termites were considered as delicate in many countries (Wood and Thomas, 1989; Hsieh and Ju, 2018).

Advances on Phylogeny of Basidiomycota

With the evidences from molecular phylogeny, Basidiomycota was shown to be a monophyletic group sister to Ascomycota (James *et al.*, 2006; Hibbett *et al.*, 2007; Zhao *et al.*, 2017), and four major clades were revealed: Agaricomycotina (mushrooms, jelly fungi, bracket fungi and others), Pucciniomycotina (rusts and others), Ustilaginomycotina (smuts and others) (Hibbett *et al.*, 2007) as well as Wallemiomycotina (Matheny *et al.*, 2006; Padamsee *et al.*, 2012; Zhao *et al.*, 2017). Higher-level classification of Basidiomycota was published around ten years ago, based mainly on a series phylogenetic studies, such as the Deep Hypha and AFTOL projects (Lutzoni *et al.*, 2004; Blackwell *et al.*, 2006; James *et al.*, 2006; Hibbett *et al.*, 2007). All of the recently introduced higher-level taxa (hereon refers to orders and above) were studied alongside related taxa. No recent study has combined all high-ranked taxa in a single phylogeny to establish whether they are well-resolved. Furthermore, a large amount of knowledge on Basidiomycota has been published in the past ten years. Numerous new species recognized, which has greatly enriched our knowledge on diversity of Basidiomycota. At the same time, related new taxonomic categories were proposed. For example, in phylogenetic studies of basidiomycetous yeasts, three new classes Malasseziomycetes, Moniliellomycetes, and Spiculogloeomycetes were introduced as well as three new orders, 16 new families, and 47 new genera (Nasr *et al.*, 2014; Wang *et al.*, 2014; Wang *et al.*, 2015a,b; Liu *et al.*, 2015).

In recent years, divergence times have been used as an additional criterion to rank taxa which have been accepted and successfully applied in many fungal systematic studies (Drummond *et al.*, 2012; Zhao *et al.*, 2016; Hongsanan *et al.*, 2017; Liu *et al.*, 2017). The following are criteria applied in these systematic studies to rank taxa above species level: (1) the taxa must be monophyletic and statistically well-supported in multi-gene analyzes; (2) their respective stem ages should be roughly equivalent, and higher taxa stem ages must be older than lower level taxa stem ages; and (3) the taxa should be identifiable phenotypically, whenever possible.

Based on the advances of systematic studies of Basidiomycota in the past ten years, we first revised the phylogenetic relationships of Basidiomycota with multigene and genomic data by a series analyzes: multi-genes phylogenetic analyzes with six genes (LSU,

SSU, 5.8 s, rpb1, rpb2, ef1) from 539 species representing 18 classes, 3 subclasses, 62 orders, 183 families and 392 genera; phyloproteomics analyzes with 396 orthologous genes from 116 species representing 17 classes and 54 orders (Zhao *et al.*, 2017); molecular dating analyzes including 771 species from 60 orders and 185 families (He *et al.*, 2019). We estimated the divergence times of Basidiomycota and propose to use following time ranges to rank taxa in Basidiomycota: subphyla should be in 406–430 Mya, classes should be in 211–383 Mya, orders should be in 99–323 Mya and families should be in 27–222 Mya (Zhao *et al.*, 2017; He *et al.*, 2019). Based on the revised phylogenetic relationships of key clades of Basidiomycota, the taxonomic status of 3198 genera names in Basidiomycota had been revised (He *et al.*, 2019).

The Taxonomic System of Basidiomycota

Historically, the taxonomic systems of fungi had been gathered in Dictionary of Fungi. The last version was published in 2008, in that version, there are 3 subphyla, 16 classes, 52 orders, 177 families, 1598 genera and 31,315 species in Basidiomycota (Kirk *et al.*, 2008). As mentioned before, numerous new taxa were published and related new taxonomic categories were proposed. Thus, the following outline of Basidiomycota was proposed which associated all these taxonomic changes of Basidiomycota.

All generic names gathered from *Index Fungorum* (2019) were checked through Kirk *et al.* (2008, 2013) and *Species Fungorum* (2019). Nomina invalida, nomina rejicienda and synonyms were excluded. There are 1928 legal genera verified with 1263 synonym names and these legal genera are taxonomically arranged. Furthermore, a brief note for each accepted genus was provided including information on their classification, number of accepted species, type species, life mode, habitat, distribution, and sequence information (He *et al.*, 2019). At present, there are 41,270 species in Basidiomycota and the most comprehensive systems of Basidiomycota including four subphyla, 18 classes, 68 orders, 241 families and 1928 genera.

Outline of Basidiomycota

Phylum Basidiomycota R.T. Moore 1980

Subphylum Agaricomycotina Doweld 2001

Class Agaricomycetes Doweld 2001

Order Agaricales Underw. 1899

Family Agaricaceae Chevall. 1826

Family Amanitaceae E.-J. Gilbert 1940

Family Bolbitiaceae Singer 1948

Family Broomeiaceae Zeller 1948

Family Biannulariaceae Jülich 1981

Family Chromocyphellaceae Knudsen 2010

Family Clavariaceae Chevall. 1826

Family Cortinariaceae R. Heim ex Pouzar 1983

Family Crassisporiaceae Vizzini, Consiglio & M. Marchetti 2019

Family Crepidotaceae (S. Imai) Singer 1951

Family Cyphellaceae Lotsy 1907

Family Cystostereaceae Jülich 1982

Overview

Cantharellales (syn. *Tulasnellales*, *Ceratobasidiales* s. auct. plur.) comprises about 629 recognized species and has a cosmopolitan distribution. Some species are economically important because of their edibility (*Cantharellus*, *Craterellus*, *Hydnum*; Watling, 1997) or being plant pathogens that cause damage in crops (Veldre *et al.*, 2013). Basidioma configuration is very diverse across *Cantharellales* (Fig. 1). Resupinate, pileate-stipitate (cantharelloid, hydroid, polyporoid), and clavarioid basidiomata are predominant, but cyphelloid species do exist. Several bulbil-forming asexual propagules belong also to *Cantharellales*. Nearly all known trophic strategies of fungi are present in *Cantharellales*. Ectomycorrhizal fungi (*Hydnaceae*) and saprotrophs constitute a significant part of the diversity of *Cantharellales*, but orchid-mycorrhizal, mycobionts with liverworts (Preußing *et al.*, 2010), lichenicolous (parasitic), lichenized and endophytic species do exist (Dearnaley *et al.*, 2016). Seemingly, there is no synapomorphic trait unique of *Cantharellales* when it is broadly circumscribed as here, *i.e.*, including *Cejpomycetaceae* and *Tulasnellaceae*. Available knowledge suggests, however, that *Cantharellales* may be split in two better defined groups that share a few, possibly synapomorphic, characters:

- (1) *Hydnaceae* and *Botryobasidiaceae*, characterized by the presence of resupinate or more complex basidioma types, and above all, the predominance of stichic basidia, often suburniform or urniform, with more than 4 sterigmata along with spores that are not repetitive. Stichic basidia, *i.e.*, with meiotic spindles parallel to the long basidial axis, appear to be universal in this group,

Fig. 1 Diversity of basidioma configuration in *Cantharellales*. (a) *Cantharellus cibarius* (*Hydnaceae*), cantharelloid basidiomata. (b) *Hydnum ellipsosporum* (*Hydnaceae*), hydroid basidiomata. (c) *Clavulina cinerea* (*Clavulinaceae*), clavarioid basidiomata. (d) *Multiclavula mucida* (*Hydnaceae*). (e) *Sistotrema confluens* (*Hydnaceae*), hydroid-polyporoid basidiomata. (f) *Sistotrema brinkmannii* (*Hydnaceae*), corticioid basidiomata. (g) undescribed clavarioid *Sistotrema*, close to *S. athelioides* (*Hydnaceae*). (h) bulbil-forming *Burgoa angulosa* (*Hydnaceae*). (i) *Botryobasidium danicum* (*Botryobasidiaceae*), corticioid basidiomata.

in contrast with the chiasitic type, with a transverse orientation of the spindle, present in nearly all other *Agaricomycetes*. Stichic basidia have hitherto been reported in *Cantharellus*, *Clavulina*, *Craterellus*, *Hydnum*, and *Multiclavula* (Juel, 1898; Donk, 1964; Restivo and Petersen, 1976; Hubbard and Petersen, 1979), while information for *Sistotrema* s.l. and *Botryobasidiaceae* is still missing. Stichic basidia are also known to be present in other basal lineages of *Basidiomycota*, such as in *Auriculariales*, *Dacrymycetales*, *Exobasidiales*, *Septobasidiales*, *Uredinales*, and *Ustilaginales* (Zmitrovich and Wasser, 2004). Basidia with more than 4 sterigmata, as opposed to the universal 4-spored condition of basidia in *Basidiomycota* might be correlated with the stichic nuclear behavior (Hibbett et al., 2014). Basidia are typically 6–8-sterigmate in *Sistotrema* s.l. and *Botryobasidium*, while 5- and 6-spored basidia are present and usually predominant in *Cantharellus*, *Craterellus*, *Hydnum* and *Multiclavula*. Exceptions are nearly all species of *Clavulina*, along with a few species of *Sistotrema* and *Craterellus*. The presence of basidia with more than 4 sterigmata is extremely unusual outside *Cantharellales* and might be related with a stichic nuclear division (Hibbett et al., 2014). Most genera possess basidia that are distinctly urniform (*Sistotrema* s.l.) or suburniform – with their broadest part in the middle or on the lower half –, the only exception being *Cantharellus* and *Craterellus* with extremely long – often exceeding 100 µm – claviform basidia. With regard to basidioma configuration, *Botryobasidiaceae* is characterized by resupinate basidiomata, whereas other basidioma types – clavarioid, cyphelloid, hydroid and cantharelloid – are represented only within *Hydnaceae* among the *Cantharellales*.

- (2) *Ceipomycetaceae* and *Tulasnellaceae*, characterized by resupinate basidiomata, and the combination of chiasitic, aseptate basidia and spores germinating by repetition. Basidia in *Tulasnella* appear to be chiasitic (Rogers, 1932) and possibly also in *Rhizoctonia* (Langer, 2001), unlike in *Hydnaceae* and possibly also in *Botryobasidiaceae*. Repetitive spores are an almost exclusive character of heterobasidiomycetes (Donk, 1964) belonging to the *Agaricomycetes* (*Auriculariales*, *Exidiales*, *Sebacinales*, *Dacrymycetales*) and *Tremellomycetes*. Nevertheless, *Oliveoniaceae* produces also holobasidia and repetitive spores, but available molecular data indicate that it nests outside *Cantharellales* (Roberts, 1998; Olariaga, unpublished). *Pseudotulasnella*, included here in *Cantharellales* and producing basidia with partial cruciate longitudinal septa, if considered phragmobasidiate, is also an exception. *Tulasnellaceae* and *Ceipomycetaceae*, however, differ in many other important respects, like in the morphology of the septal pore (see below). Further, basidia in *Tulasnellaceae* have inflated sterigmata that may be evolutionarily interpreted as phragmobasidia.

The septal pore morphology shows also variation within *Cantharellales* and has been used to infer relationships. While *Botryobasidium* and *Tulasnella* possess imperforate parentheses, *Cantharellus* and *Sistotrema*, and at least some species of *Rhizoctonia* have perforate parentheses, among which a great diversity in pore openings exists as well (Van Driel et al., 2009). At present, it is uncertain whether septal pore morphologies are useful to depict monophyletic lineages within *Cantharellales*.

Phylogenetic Incongruences, Family Classification and The Polyphyly of *Sistotrema*

Cantharellales was first recognized by Hibbett and Thorn (2001, called then cantharelloid clade) for a morphologically diverse assemblage of fungi recovered as monophyletic in studies based on nuclear ribosomal regions (Brunns et al., 1998; Hibbett et al., 1997; Pine et al., 1999). Moncalvo et al. (2006) showed that nuclear ribosomal regions are involved in phylogenetic conflicts due to an accelerated rate of evolution and cause long-branch attraction problems. Although 4 monophyletic lineages – *Hydnaceae*, *Ceipomycetaceae*, *Tulasnellaceae*, *Botryobasidiaceae* – are consistently retrieved in phylogenetic studies, the relationships among these remain unclear and are strongly dependent upon the genetic marker, taxon sampling and the type of phylogenetic analysis implemented for inference (Fig. 2). As an example, *Tulasnellaceae* is sister to the *Cantharellus*-*Craterellus* clade when nuclear ribosomal regions are employed for phylogenetic inference (Moncalvo et al., 2006), but *Tulasnellaceae* is sister to *Botryobasidiaceae* when the mtSSU region is employed (Hibbett and Thorn, 2001). When the RPB2 region is utilized for phylogenetic reconstruction, the position of *Tulasnellaceae* is basal to the rest of the *Cantharellales* (González et al., 2016) or sister to *Hydnaceae*, being *Botryobasidiaceae* and *Ceipomycetaceae* the basal lineages in *Cantharellales* (Matheny et al., 2006). Phylogenetic incongruences also affect relationships within the *Hydnaceae* and the sister groups of *Hydnum*, *Sistotrema confluens* and *Cantharellaceae*, are different depending on the region analysed.

In this scenario, family classification proposals up to present are not founded on robust phylogenetic hypotheses employing an adequate taxon sampling. *Tulasnellaceae* is sometimes treated at the order rank as *Tulasnellales* and placed outside *Cantharellales* (Begerow et al., 2018). The families *Cantharellaceae*, *Sistotremataceae*, *Hydnaceae* and *Clavulinaceae* are sometimes accepted, albeit relationships and delimitation among these are unclear. *Botryobasidiaceae* is currently recognized but it could be merged with *Ceipomycetaceae* if both form a monophyletic group (González et al., 2016). The phylogenomic reconstruction by Nagy et al. (2016) placed *Ceipomycetaceae* in a basal position to the clade formed by *Tulasnellaceae* and *Botryobasidiaceae*, by sampling only 3 species of *Cantharellales*. This phylogenetic hypothesis, thus, needs to be tested using a more comprehensive taxon sampling. A conservative approach until phylogenomic analyses that address current phylogenetic incongruences appropriately become available is to recognize the 4 main lineages of *Cantharellales* at family level: *Botryobasidiaceae*, *Hydnaceae* (syn. *Cantharellaceae*, *Clavulinaceae*, *Sistotremataceae*), *Ceipomycetaceae* (*Ceratobasidiaceae* s. auct., see Oberwinkler et al. (2013)), and *Tulasnellaceae*, as done by Hibbett et al. (2014) and followed here.

Comparative genomics of early-diverging mushroom-forming fungi provides insights into the origins of lignocellulose decay capabilities. *Molecular Biology and Evolution* 33, 959–970.

A further major problem in naming many genera within the core of the cantharelloid clade is that *Sistotrema* s.l. is composed of at least 4 polyphyletic lineages (Moncalvo *et al.*, 2006) and that several monotypic or oligotypic bulbil-forming genera belong to these as well (Lawrey *et al.*, 2007). The type species of *Sistotrema*, *S. confluens*, along with other species with an irpicoid-poroid hymenophore, is ectomycorrhizal and suggested to be closely related to *Hydnum* (Moncalvo *et al.*, 2006), rather than to the rest of *Sistotrema* species, which mostly have similar urniform 4–8-spored basidia, saprotrophic habit and resupinate basidiomata (Bernichia and Pérez-Gorjón, 2010). Corticioid *Sistotrema* species appear in 5 paraphyletic lineages, the first four recognized by Moncalvo *et al.* (2006): (a) *S. brinkmannii-oblongisporum* group, *Burgoa moriformis*, *Burgella* and *Rogersiomyces malaysianus* (*Sistotrema* I), apparently close to *Clavulina*, (b) *S. athelioides* (*Sistotrema* II), (c) *S. adnatum*, *Minimedusa* and *Bryoclavula phycophila* (*Sistotrema* III), (d) *S. eximum-octosporum* group (*Sistotrema* IV), and (e) *Sistotrema raduloides* (*Sistotrema* V). As before, a robust phylogenetic hypothesis that elucidates the relationships among all these lineages is lacking, partly due to the fact that only nuclear ribosomal sequences are available for bulbil-forming species (*e.g.*, Lawrey *et al.*, 2007) and newly described species (Purtseva *et al.*, 2016; Masumoto and Degawa, 2020) and that several basal nodes supported in the phylogeny by Moncalvo *et al.* (2006), Fig. 2(A) lose support when these are included due to increased missing data.

Diversity, Current Knowledge and Issues in Species Delimitation

Previous species estimates (Hibbett *et al.*, 2014, 260 sp.; Begerow *et al.*, 2018, 541 sp.; He *et al.*, 2019, 589 sp.) were considerably lower than our current estimate of 629 described and recognized species belonging to *Cantharellales*. The much higher amount of OTUs in the UNITE database – 1824 OTUs when most conservative threshold of 3% is applied – suggests that the actual diversity of *Cantharellales* is considerably higher (Nilsson *et al.*, 2018, consulted on 23rd August 2020). This estimate must be, however, interpreted with caution, as the accelerated rate of evolution of nuclear ribosomal markers in some groups of *Cantharellales* (Moncalvo *et al.*, 2006), or possible errors in sequences (Haas *et al.*, 2011; Hughes *et al.*, 2015; Aas *et al.*, 2017), may have caused an overestimation. In contrast, it is known that a low number of described species have been sequenced for the ITS region (Nilsson *et al.*, 2006) and thus, one would expect the number of OTUs to increase as sequences of these are incorporated to public sequence databases. Poorly known groups and other issues are discussed below.

Ectomycorrhizal species with fleshy basidiomata of the core of the cantharelloid clade (*Cantharellus*, *Craterellus*, *Hydnum*, *Clavulina*) account for more than a half of the described diversity (336 accepted species). These genera share a similar taxonomic

intricacy, its species showing a considerable macroscopical plasticity but limited microscopical diversity compared to other fungal groups (Buyck, 2016; Olariaga *et al.*, 2009). Usual taxonomic problems in these genera are that several close species are subsumed under a single name and that European names are often misapplied to taxa occurring in other continents, while many taxa, possibly most, are continental endemics (Buyck *et al.*, 2014; Niskanen *et al.*, 2018; Olariaga *et al.*, 2017; Thacker and Henkel, 2004). Molecular data are being decisive for delineating limits between sibling species. Of these *Hydnum* and *Cantharellus* are better known and in constant state of flux, but the diversity of *Clavulina* and *Craterellus* is not well understood yet, especially in the tropics.

Also, soil-inhabiting and mycorrhizal endophytic *Cejpomycetaceae* and *Tulasnellaceae* associated with orchid roots, often called “Rhizoctonias” (Dearnaley *et al.*, 2016), harbor certainly a considerably higher diversity than known today. The majority of orchids investigated associate exclusively with a few fungal partners – rarely only one (Bougourel *et al.*, 2009) – across its distribution range (Dearnaley *et al.*, 2016). Although many “Rhizoctonias” appear not to be highly host specific (Veldre *et al.*, 2013), at least some endophytic *Tulasnellaceae* are only known from a single orchid genus (Linde *et al.*, 2017). As new orchid hosts are screened for “Rhizoctonias”, undescribed species are being continuously detected (e.g., Fujimori *et al.*, 2019; Linde *et al.*, 2017; Silva Freitas *et al.*, 2020) and further sampling, especially in tropical areas, will probably yield the discovery of many novel species (Veldre *et al.*, 2013). An important part of the operational taxonomic units (OTUs) discovered remains unnamed (e.g., Jacquemyn *et al.*, 2012; Oja *et al.*, 2015; Smith *et al.*, 2010) as these studies are mainly based on environmental sequencing techniques and no physical specimens were available for typification of new taxa. Endophytic “Rhizoctonias” associated with liverworts are less diverse than orchid associates but remain likewise largely unexplored (Bidartondo and Duckett, 2010).

The problems in determining how many of the accepted of phytopathogenic species of *Rhizoctonia* s. str. (*Ceratobasidium* s. auct., see Oberwinkler *et al.*, 2013) have been formally described adds uncertainty to the estimation of the known number of species within *Cantharellales*. *Rhizoctonia* s.l. has been conventionally used to accommodate anamorphic states of *Botryobasidium*, *Ceratobasidium* s. auct. and *Tulasnella* (Stalpers and Andersen, 1996). Andersen and Stalpers (1994) revised 117 epithets then available in *Rhizoctonia* and considered that 41 of these belonged to *Rhizoctonia* s. str. based on morphological characters. Nevertheless, morphological characters are of limited value in delineating species boundaries (Roberts, 1999; Vilgalys and Cubeta, 1994). To undertake species delimitation, plant pathologists have developed instead a method based on the number of nuclei per cell and a biological species recognition approach, i.e., “anastomosis group concept” (referred to as AG) (Matsumoto *et al.*, 1932), based on the ability of isolates of the same species to recognize and fuse with each other in co-culture. This approach has also some limitations (Sharon *et al.*, 2008). Based on the AG concept, at least 29 groups have been recognized some of which have been further divided into subgroups (Sharon *et al.*, 2008), but most of these have not been linked to the binomial nomenclature. While most of these AGs have received phylogenetic support (Sharon *et al.*, 2008), other studies have shown that some AGs are polyphyletic, i.e., strains assigned to the same AG do not form monophyletic groups. Veldre *et al.* (2013) recovered 52 OTUs of plant pathogenic species based on the analysis of all ITS sequences available then in public databases but assigned a binomen to only one of these. Meanwhile a serious effort to link sequences obtained from type specimens or ex-type cultures and described AGs is not made, this issue will remain opened.

Based on all of this, it is concluded here that *Cantharellales* may comprise at least 1500 species, more than a half of which is still undescribed.

Trophic Strategies

Cantharellales is an ecologically very diverse order, in which saprotrophic groups and a broad array of symbiotic relationships (mycorrhizal, lichenized, parasitic, endophytic) exist (Hibbett *et al.*, 2014). Although the exact story of nutritional transitions cannot be determined with certainty in the absence of a robust phylogenetic hypothesis, it is likely that the common ancestor was saprotrophic (Martin *et al.*, 2016) and resupinate.

Saprotrophic *Cantharellales* are usually species with resupinate basidiomata, present in all the families recognized here and can be easily cultured in common agar media (e.g., Langer, 1994; Matsumoto *et al.*, 1932; Warcup, 1985) due to their saprotrophic abilities, sometimes in addition to other lifestyles. Interestingly, no primary wood decayers exist in *Cantharellales* and most saprotrophic species occur in soft wood or plant remnants in advanced stage of decay. Saprotrophic *Cantharellales* have been claimed to cause an ancestral “soft rot” and to have the plesiomorphic decay mode of the Agaricomycetes, characterized by having diverse repertoires of gene families involved in cellulose decomposition but lacking key enzymes of lignine decomposition. *Botryobasidium* has been claimed to possess a limited ability to degrade wood and to function as a carbohydrate scavenger in white rot fungal communities or suggested to be a mycorrhizal symbiont (Nagy *et al.*, 2016). Those conclusions have been drawn by analyzing a handful of species.

Ectomycorrhizal *Cantharellales* usually form complex non-resupinate basidiomata and are almost exclusively found in *Hydnaceae* and belong to presumed obligate genera of ectomycorrhizal fungi, such as *Cantharellus*, *Clavulina*, *Craterellus*, *Hydnum* and *Sistotrema* s. str. (Tedersoo *et al.*, 2010 and references therein). In vitro cultures have been successfully obtained from basidiospores (Itävaara and Willbeg, 1988) and ectomycorrhizal root tips (Ogawa *et al.*, 2019) in *Cantharellus* and from basidioma tissue in *Hydnum repandum* (Peksen *et al.*, 2013). The notably low $\delta^{15}\text{N}$ value found in *Clavulina cristata* suggests that species of *Clavulina* have saprotrophic abilities (Trudell *et al.*, 2004). Basidiomata of fleshy *Hydnaceae*, as it is well documented in *Cantharellus*, are unusually long-lived (Largent and Sime, 1995; Norvell, 1995) and resistant against insect predation (Pilz *et al.*, 2003), probably

due to its insecticidal properties (Masota *et al.*, 2017). Two lineages of *Ceipomycetaceae* (Veldre *et al.*, 2013) and some species of *Tulasnellaceae* are also known to facultatively produce ectomycorrhizae (Tedersoo *et al.*, 2010 and references therein; Tedersoo and Smith, 2013) with ectomycorrhizal plant hosts, whereas they form endomycorrhizae with orchids (Warcup, 1985) or are able to establish symbiotic associations with hepatics by colonizing their rhizoids (Bidartondo *et al.*, 2003). Mycorrhizal associations produced by species of *Cantharellales* show a low host specificity (Pilz *et al.*, 2003) and are able to associate with plants of different genera and families if those are available. Danell (1994) reported that *Cantharellus formosus* can establish ectomycorrhizal associations with 14 plant genera. In Europe, *C. pallens* occurs mainly in association with *Pinaceae* and *Fagaceae*, but also with *Cistaceae* (Vila and Llimona, 2009, as *C. aff. cibarius*) and *Ericaceae*, while *C. romagnesianus* has been recorded with *Pinaceae* and *Fagaceae* (Olariaga *et al.*, 2017) but also forms putative ectomycorrhizae with planted *Eucalyptus* trees (*Myrtaceae*; Olariaga, 2009). Well-known species of *Clavulina*, *Craterellus*, and *Hydnum* constitute further examples of broad host ranges (Olariaga, 2009). Species putatively restricted to a tree genus have also been mentioned (Redhead *et al.*, 1997), but the confirmation of a strict association requires further experimental evidence. A unique “ectomycorrhiza-like” interaction has been described between *Cantharellus tropicalis* and *Dendrocalamus strictus* (*Poaceae*) and even synthesized *in vitro* (Sharma *et al.*, 2011).

Other mycorrhizal interactions with orchids occur in “Rhizoctonias” belonging to *Tulasnellaceae* and *Ceipomycetaceae*, as well as in some other fungal groups (Dearnaley *et al.*, 2012). *Tulasnellaceae* appear to be the most frequently recorded orchid associates (Jaquemyn *et al.*, 2017; Yuan *et al.*, 2010). Orchid mycorrhizas are unusual in that, compared to other mycorrhizal associations, orchids protocorms (heterotrophic, achlorophyllous stage after seed germination) are heterotrophic and obtain carbon and other nutrients from the mycobiont (Dearnaley *et al.*, 2012; Smith and Read, 2008). When adult orchids develop photosynthetic capability, they continue to benefit from the associated fungus by obtaining mineral nutrients. Although the nature of this type of mycorrhizal association has been suggested to be mutualistic (Cameron *et al.*, 2006, 2008), the carbon flow is sometimes from orchid to the fungus, whereas evidence supporting that some adult orchids obtain carbon from fungi is also available (Selosse and Roy, 2009; Yagame *et al.*, 2012). Symbiotic “Rhizoctonias” colonize the space between the cell wall and the plasmatic membrane, shaping coiled structures known as pelotons (Dearnaley *et al.*, 2012), where the nutrient exchange is very likely to occur. As orchid mycobionts are easily isolated *in vitro* – most, probably all, have an additional saprotrophic or parasitic lifestyle –, orchid mycobionts could be only linked to teleomorphic genera in the rare occasions in which teleomorphic states are successfully induced in axenic cultures. Thus, most orchid associated *Cantharellales* were assigned to two genera encompassing asexual morphs, *Ceratorhiza* and *Epulorhiza*, which became synonyms of *Rhizoctonia* and *Tulasnella*, respectively, with the end of dual nomenclature in fungi. Currently, the use of molecular data is helping to understand the high diversity of orchid-associated *Cantharellales* (e.g., Fujimori *et al.*, 2019; Linde *et al.*, 2017; Silva Freitas *et al.*, 2020). A mycorrhizal association has been also suggested between *Botryobasidium* and the orchid genus *Apostasia* (Yukawa *et al.*, 2009), but this putative relationship should be explored further. Mycorrhiza-like interactions between *Tulasnellaceae* and liverworts have been also documented in hepatics of the family *Aneuraceae* (Bidartondo *et al.*, 2003; Kottke *et al.*, 2003) and have been defined as a model or early evolved symbiotic associations (Krause *et al.*, 2011).

Lichenization with green unicellular algae has evolved two times in *Cantharellales*, in the genera *Multiclavula* and *Bryoclavula* (Masumoto and Degawa, 2020). Both lineages share minute clavarioid basidiomata and more or less urniform basidia that often produce more than four basidiospores. The thallus can be rather conspicuous, continuous or formed by scale-like or granular units (Oberwinkler, 2012). Globose hyphal-algal associations are characteristic of *Multiclavula* (Oberwinkler, 1980), while in *Bryoclavula* mycelial hyphae surround photobiont cells. Haustoria are not produced (Masumoto and Degawa, 2020; Oberwinkler, 2012). The association with algae seems obligatory in both cases. Although both lineages share striking similarities, analyses of the 28S or the nuclear rDNA suggest that *Multiclavula* is nested in the *Sistotrema* I clade (Moncalvo *et al.*, 2006), whereas *Bryoclavula* is supported in the *Sistotrema* III clade (Masumoto and Degawa, 2020). As discussed above, a more robust phylogeny is needed to further test this phylogenetic hypothesis too. Some species accommodated in *Multiclavula* may belong to *Lepidostromataceae*, in the *Hygrophoraceae*, due to having up to 4-spored claviform basidia (Oberwinkler, 2012), and likely a chiasitic nuclear behavior unlike *Multiclavula*.

Although basidiomycetous endophytes are underrecorded (Martin *et al.*, 2015), some *Ceipomycetaceae* and *Tulasnellaceae* are known to be widespread endophytes in a broad variety of plants that occur in different environments, such as in leaves (Martin *et al.*, 2015), roots of orchids (Racharin *et al.*, 2018) and other plants (e.g., Cosoveanu and Cabrera, 2018; Sen *et al.*, 1999), even in saline environments (Soares *et al.*, 2016) or ferns (Younginger and Ballhorn, 2017). As with other endophytic fungi, little is known about the frequency or the possible commensalistic or mutualistic nature of endophytic *Cantharellales* (Sen *et al.*, 1999).

A parasitic nutrition strategy occurs mainly in *Rhizoctonia*, in which the asexual *R. solani* is a common, problematic pathogen on a broad range of crops (Veldre *et al.*, 2013). *Rhizoctonia* attacks primarily roots and stem bases of herbaceous plants and produces occasionally its sexual stage on infected plants. Asexual bulbilliferous *Cantharellales* – *Adamflackia*, *Burgella*, *Burgoa*, *Minimedusa*, etc. – are also considered weak parasites on lichens (Diederich and Lawrey, 2007). As *Sistotrema*-like urniform basidia have been observed in cultures of *Burgoa* species (Weresub and LeClair, 1971), bulbilliferous *Cantharellales* are linked to saprotrophic *Sistotrema* species, and therefore, appear to be facultative parasites.

Synopsis

Botryobasidiaceae Jülich 1982.

Botryobasidium Donk 1931 (syn. *Acladium* Link 1809, *Alysidium* Kunze 1817, *Haplotrichum* Link 1824, *Allescheriella* Henn. 1897, *Botryohypochnus* Donk 1931, *Cyanohypha* Jülich 1982). Basidiomata resupinate, thin. Hyphae cylindrical, without ampullaceous septa. Dolipores with perforate parentheses. Clamps present or absent. Leptocystidia seldom present. Basidia broadly claviform to suburniform, usually shorter than 20 µm, 4–8-spored, with a stichic nuclear division. Basidiospores smooth or ornamented, thin or thick-walled, sometimes cyanophilous. Anamorphs of *Haplotrichum*, *Allescheria* or *Alysidium* type. Saprotrophic, suggested to be mycorrhizal. Lignicolous on very decayed wood, seldom on bare ground. Cosmopolitan. The name *Botryobasidium* would need to be conserved against older priority synonyms for its continued usage.

Suillosporium Pouzar 1958. Basidiomata resupinate, porulose to odontoid. Hyphae short-celled in the subhymenium, without ampullaceous septa. Clamps present. Septocystidia present. Basidia broadly claviform, usually shorter than 20 µm, 4-spored, with unknown nuclear division. Basidiospores smooth, not repetitive. Anamorph unknown. Saprotrophic, lignicolous on very decayed wood. North hemisphere, south America, Mascarenes and Réunion islands. Molecular data unavailable; 4-spored basidia suggest a placement elsewhere.

Ceipomycetaceae Jülich 1982 (syn. *Ceratobasidiaceae* Martin 1948 sensu auct.).

Rhizoctonia DC 1815 (= *Thanatephorus* Donk 1956). Basidiomata resupinate, thin, sometimes producing sclerotia. Hyphae cylindrical, occasionally moniloid, without ampullaceous septa. Dolipores with perforate parentheses. Clamps present or absent. Leptocystidia mostly absent. Basidia cylindrical to claviform, usually shorter than 20 µm, 2–4-spored, possibly chastic. Basidiospores smooth or ornamented, thin or thick-walled, sometimes repetitive. Anamorphs of *Rhizoctonia* type, rarely bulbiliferous. Saprotrophic, parasitic, ectomycorrhizal or orchid mycorrhizal. Basidiomata found on very decayed wood. Cosmopolitan.

Hydnaceae Chevall. 1826 (syn. *Cantharellaceae* J. Schröt. 1888, *Clavulinaceae* Donk 1970, *Sistotremataceae* Jülich 1982).

Adamflackia (Diederich and Lawrey, 2007). Bulbilliferous, basidiomata and conidiomata unknown. Bulbils beige to orange, without hairs, surface cells polyhedral, internal cells roundish to polyhedral. Hyphae thin-walled. Clamps absent. Lichenicolous. South America.

Bryoclavula (Masumoto and Degawa, 2020). Basidiomata clavarioid, minute. Hyphae cylindrical, without ampullaceous septa. Clamps present. Cystidia absent. Basidia clavate to suburniform, mostly 4–6-spored. Basidiospores smooth, narrowly ellipsoid, thin-walled. Lichenized on rocks, associated with green coccoid algae. Japan.

Burgella (Diederich and Lawrey, 2007). Bulbilliferous, basidiomata and conidiomata unknown. Bulbils yellow or honey-colored, without hairs, cells in surface polyhedral. Hyphae thin-walled. Clamps present. Lichenicolous. North and South America.

Burgellopsis (Diederich and Lawrey, 2007). Bulbilliferous, basidiomata and conidiomata unknown. Bulbils white, without hairs, internal cells roundish to polyhedral. Hyphae thin-walled. Clamps absent. Lichenicolous. Europe.

Cantharellus Adans. 1763, *nom. sanct.* (syn. *Goossensia*, *Afrocantharellus*). Basidiomata pileate-stipitate, plane or depressed, usually thick-fleshed, seldom cyphelloid, with bright colors. Hymenophore smooth to veined. Hyphae cylindrical or inflated, without ampullaceous septa. Clamps present or absent. Cystidia absent. Basidia claviform, usually exceeding 100 µm, generally 4–6-spored, with a stichic nuclear division. Basidiospores ellipsoid, smooth. Ectomycorrhizae with unbranched rhizomorphs. Carotenoids bicyclic. Cosmopolitan.

Clavulina Schrot. 1888 (syn. *Membranomyces* 1975). Basidiomata clavarioid, sometimes resupinate, rarely cantharelloid. Hyphae cylindrical to inflated, without ampullaceous septa. Clamps present or absent. Leptocystidia present in a few species, occasionally encrusted. Basidia claviform to suburniform, older basidia with a cross secondary septum, typically 2-spored, 4–6-spored in a few species, stichic. Basidiospores usually ovoid, with a large guttule. Ectomycorrhizal, with saprotrophic ability as suggested by isotope ratios. Cosmopolitan.

Craterellus Pers. 1825, *nom. sanct.* (syn. *Pseudocraterellus* 1958, *Pterygellus* 1966). Basidiomata pileate-stipitate, depressed to infundibuliform, usually thin-fleshed, nearly always with a hollow stipe. Hymenophore smooth to veined. Hyphae cylindrical or inflated, without ampullaceous septa. Clamps absent or present. Cystidia absent. Basidia claviform, usually exceeding 100 µm, 2–6 (8)-spored, stichic. Ectomycorrhizae without rhizomorphs. Carotenoids aliphatic. Cosmopolitan.

Hydnum L. 1753, *nom. sanct.* Basidiomata pileate-stipitate, usually with an ocher or orange-red pileus. Hymenophore odontoid. Hyphae inflated, with ampullaceous septa in the basal mycelium. Clamps present. Cystidia absent. Basidia suburniform, generally 3–7-spored, stichic. Basidiospores smooth, ellipsoid to nearly globose. Ectomycorrhizal. With cytotoxic diepoxides. Cosmopolitan.

Multiclavula Petersen 1967. Basidiomata clavarioid, minute, simple, white to orange. Hyphae cylindrical to slightly inflated, thin-walled to somewhat thick-walled, without ampullaceous septa. Clamps present or absent. Cystidia absent. Basidia suburniform, 2–8-spored, with at least some basidia with more than 4 spores in several species. Basidiospores cylindrical to ovoid. Lichenized on soil or wood, associated with green coccoid algae. Cosmopolitan.

Neoburgoa (Diederich and Lawrey, 2007). Bulbilliferous, basidiomata and conidiomata unknown. Bulbils yellow to orange, without hairs, internal cells roundish to polyhedral. Hyphae thick-walled. Clamps present in culture. Lichenicolous. Europe.

Sistotrema Fr. 1821, *nom. sanct.* (syn. *Hydnotrema* 1833, *Burgoa* 1937, *Urnobasidium* 1968, *Minimedusa* 1971, *Ingoldiella* 1972,). Basidiomata usually resupinate, smooth, odontoid or poroid, seldom stipitate-pileate or clavarioid. Hyphae cylindrical to inflated, sometimes with ampullaceous septa, especially in the rhizomorphs. Cystidia seldom present as leptocystidia or gloeocystidia. Basidia characteristically urniform, 2–8-spored, usually with more than 4 sterigmata, presumably stichic. Basidiospores usually ellipsoid to allantoid, not repetitive. Anamorphs bulbilliferous or hyphomycetous. Saprotrophic or ectomycorrhizal. Cosmopolitan. Polyphyletic, in need of rearrangement, treated here in a conventional sense.

Tulasnellaceae (Juel, 1898) (syn. *Gloeotulasnella* Höhn and Litsch. 1908).

Pseudotulasnella Lowy, 1964. Basidiomata resupinate, waxy-gelatinous. Hyphae cylindrical, thin-walled. Clamps absent. Cystidia absent. Basidia with longitudinal cruciate partial septa, with inflated sterigmata (epibasidia). Basidiospores repetitive. Saprotrophic. South America.

Tulasnella Schröt, 1888. Basidiomata resupinate, smooth, waxy to subgelatinous, sometimes producing sclerotia. Hyphae cylindrical, thin to thick-walled, sometimes monilioid. Clamps present or absent. Dolipore with continuous parentheses. Leptocystidia sometimes present. Basidia holobasidiate, with inflated sterigmata (epibasidia). Basidiospores cylindrical to allantoid, sometimes sigmoid, repetitive. Anamorphs of *Rhizoctonia* or *Epulorhiza* type. Saprotrophic, ectomycorrhizal or orchid mycorrhizal. Basidiomata found on decayed wood. Cosmopolitan.

Stilbotulasnella Oberw. and Bandoni, 1982. Basidiomata composed of conidiophores, later forming sporodochia. Conidia blastic, annelidic. Hymenium absent. Hyphae cylindrical thin-walled. Clamps absent. Dolipores without parentheses. Basidia holobasidiate, with inflated sterigmata (epibasidia). Basidiospores ellipsoid, repetitive. Saprotrophic, foliicolous. North America.

Families Previously Included in *Cantharellales* and Excluded Here

Aphelariaceae Corner, 1970.

This family encompasses species that produce clavarioid basidiomata and that lack any of the typical characters of *Cantharellales*. Basidia in *Aphelariaceae* are short and claviform, 4-spored, ampullaceous septa are absent and spores are not repetitive. Molecular data of the type *Aphelaria*, *A. dendroides*, are needed to propose a better phylogenetic placement. In the meantime, it is excluded here from *Cantharellales*.

Oliveoniaceae Roberts, 1998

Combined analyses of the RPB1-RPB2-EF regions indicate that *Oliveonia* belongs to the *Auriculariales*, outside *Cantharellales* (Olariaga, unpublished) and it is accordingly excluded here.

Genera previously included in Cantharellales and excluded here.

Ceratobasidium Rogers 1932.

Corallofungus Kobayasi 1983.

Gloeomucro Petersen 1980.

Odontiochaete Rick 1940.

Parastereopsis Corner 1976.

Paullicorticium Erikss 1958.

Repetobasidiellum Erikss and Hjortstam 1981.

Repetobasidium Erikss 1958.

Radulochaete Rick 1940.

Schildia Franchi and Marchetti 2015.

Waitea Warcup 1985.
